THIRTEENTH EDITION

DEVELOPMENT THROUGH LIFE

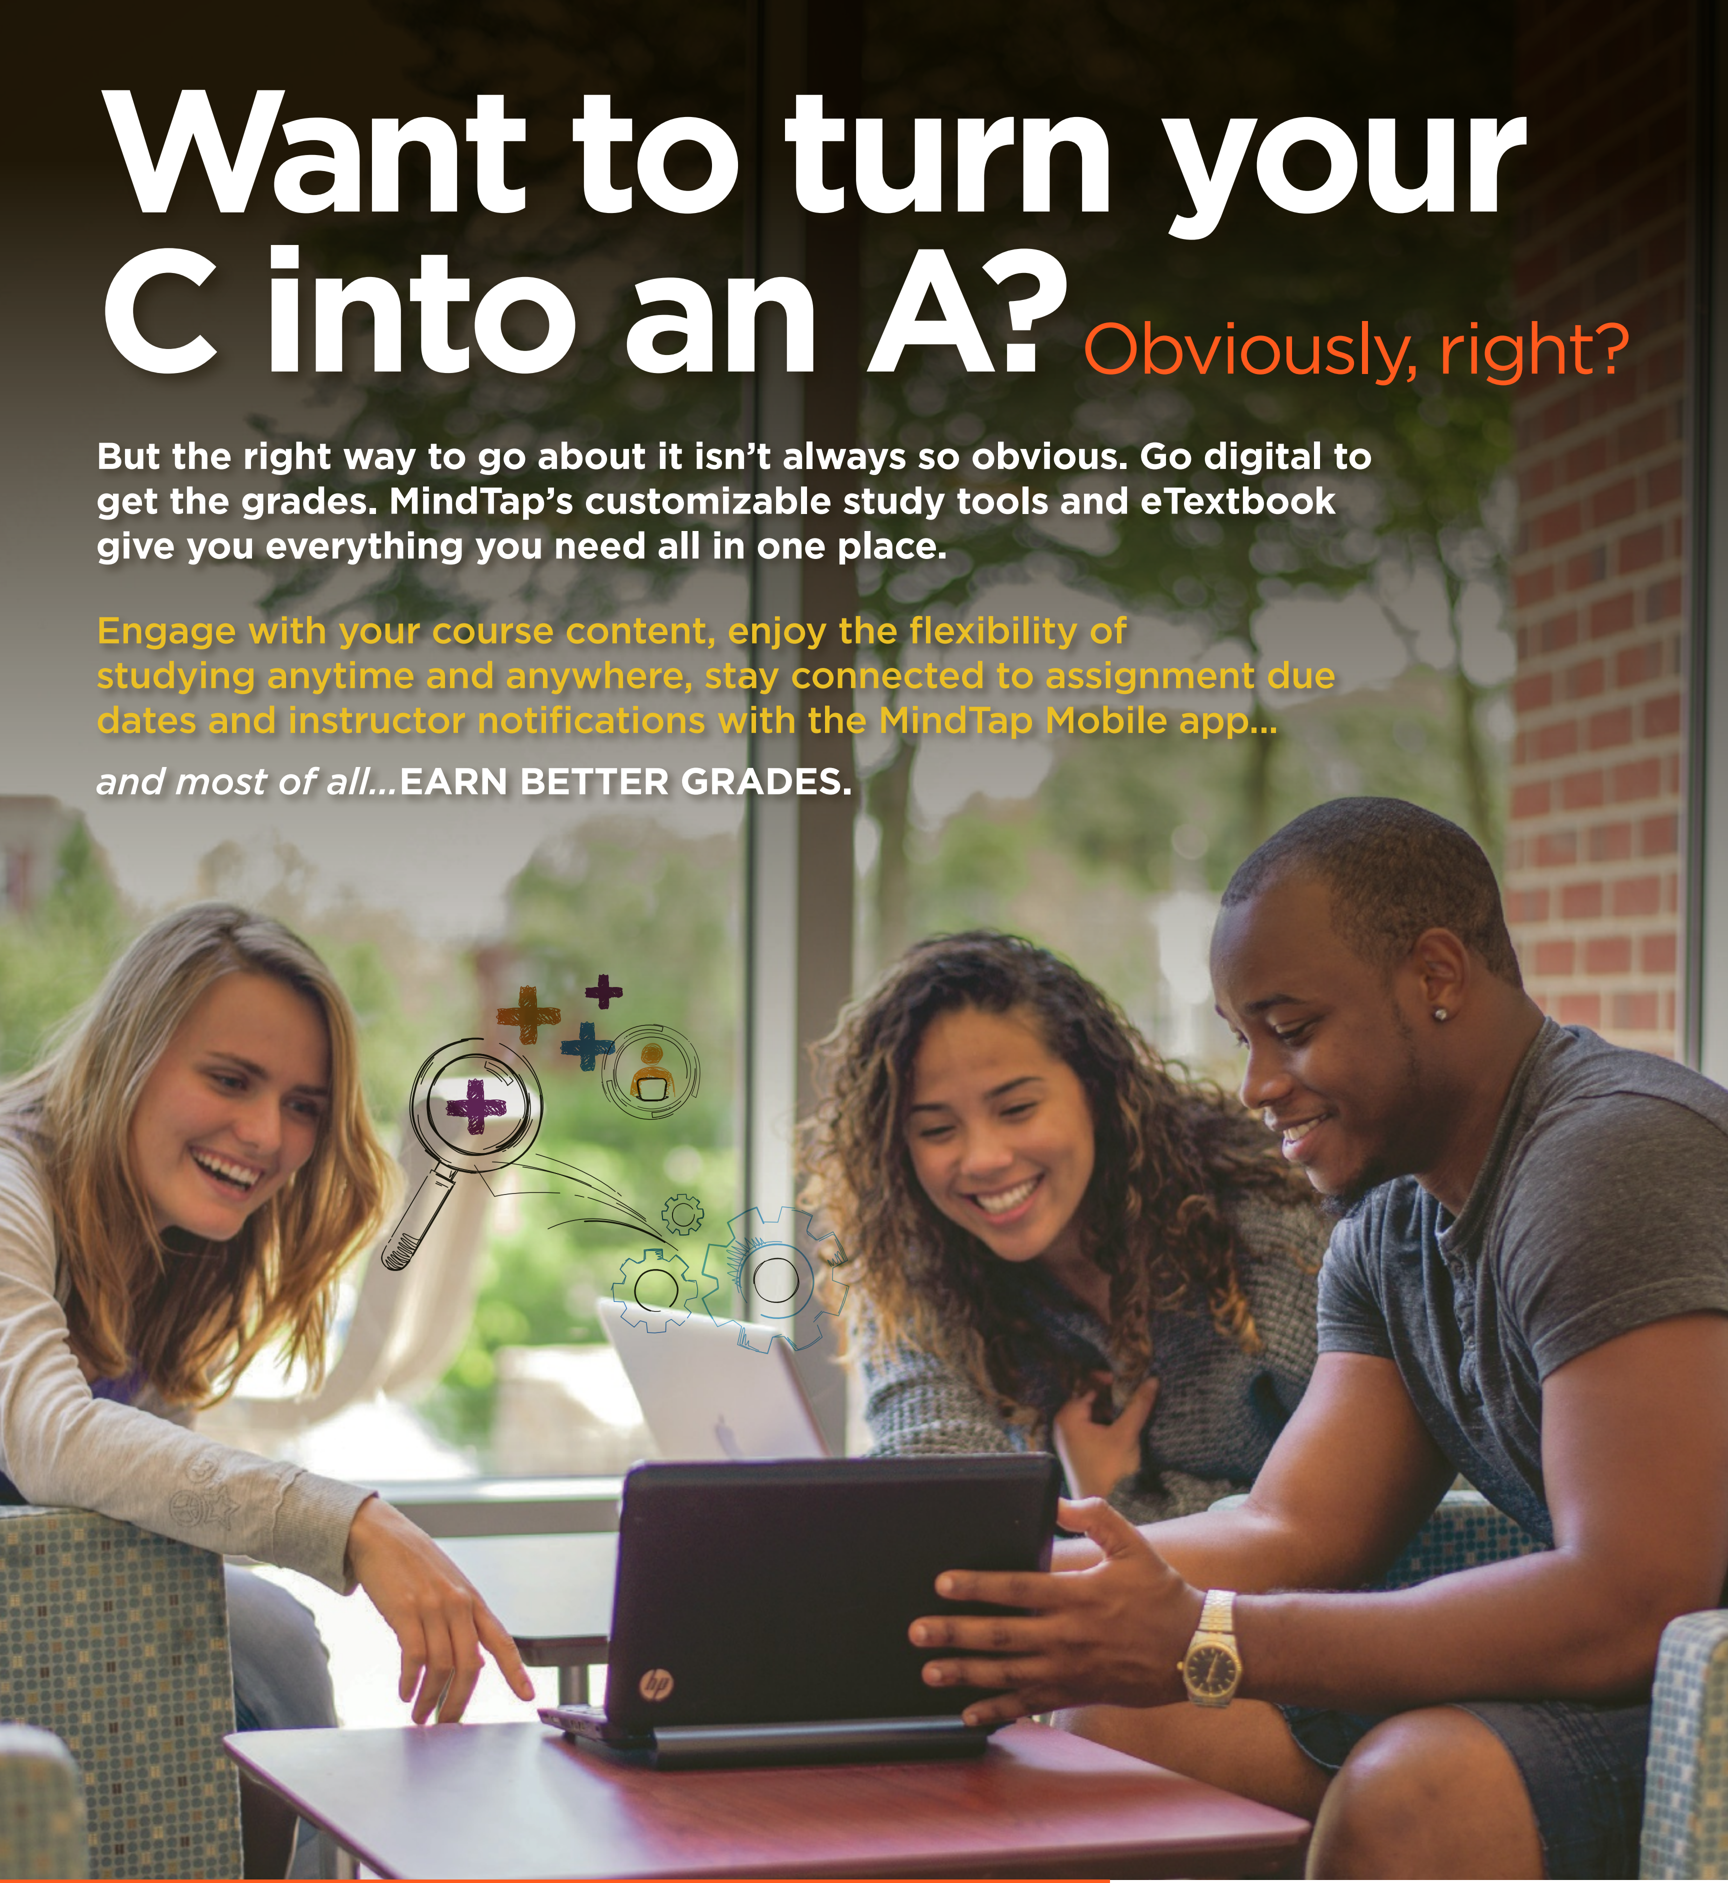
A Psychosocial Approach

Newman : Newman

THE ORGANIZATION OF THE TEXT

LIFE STAGE	DEVELOPMENTAL TASKS	PSYCHOSOCIAL CRISIS
PRENATAL **(Conception to birth)** *Chapter 4*		
INFANCY **(First 24 months)** ***Chapter 5***	Maturation of sensory/perceptual, and motor functions Sensorimotor intelligence: Processing, organizing and using information Communication Attachment Emotional development	Trust versus mistrust
TODDLERHOOD **(2 to 4)** ***Chapter 6***	Elaboration of locomotion Language development Fantasy play Self-control	Autonomy versus shame and doubt
EARLY SCHOOL **Age (4 to 6)** ***Chapter 7***	Gender identification Early moral development Self-theory Peer play	Initiative versus guilt
MIDDLE CHILDHOOD **(6 to 12)** ***Chapter 8***	Friendship Concrete operations Skill learning Self-evaluation Team play	Industry versus inferiority
EARLY ADOLESCENCE **(12 to 18)** ***Chapter 9***	Physical maturation Formal operations Emotional development Membership in the peer group Romantic and sexual relationships	Group identity versus alienation
LATER ADOLESCENCE **(18 to 24)** ***Chapter 10***	Autonomy from parents Gender identity Internalized morality Career choice	Individual identity versus identity confusion
EARLY ADULTHOOD **(24 to 34)** ***Chapter 11***	Exploring intimate relationships Childbearing Work Lifestyle	Intimacy versus isolation
MIDDLE ADULTHOOD **(34 to 60)** ***Chapter 12***	Managing a career Nurturing an intimate relationship Expanding caring relationships Managing the household	Generativity versus stagnation
LATER ADULTHOOD **(60 to 75)** ***Chapter 13***	Accepting one's life Promoting intellectual vigor Redirecting energy toward new roles Developing a point of view about death	Integrity versus despair
ELDERHOOD **(75 until death)** ***Chapter 14***	Coping with the physical changes of aging Developing a psychohistorical perspective Traveling uncharted territory: Life structures of the very old	Immortality versus extinction

CENTRAL PROCESS	PRIME ADAPTIVE EGO QUALITY	CORE PATHOLOGY	APPLIED TOPIC
			Abortion
Mutuality with the caregiver	Hope	Withdrawal	The role of the parents
Imitation	Will	Compulsion	Child care
Identification	Purpose	Inhibition	School readiness
Education	Competence	Inertia	Violence in the lives of children
Peer pressure	Fidelity to others	Dissociation	Adolescent alcohol and drug use
Role experimentation	Fidelity to values	Repudiation	Dropping out of college
Mutuality among peers	Love	Exclusivity	Divorce
Person-environment interaction and creativity	Care	Rejectivity	Discrimination in the workplace
Introspection	Wisdom	Disdain	Retirement
Social support	Confidence	Diffidence	Meeting the needs of the frail elderly



Want to turn your C into an A? Obviously, right?

But the right way to go about it isn't always so obvious. Go digital to get the grades. MindTap's customizable study tools and eTextbook give you everything you need all in one place.

Engage with your course content, enjoy the flexibility of studying anytime and anywhere, stay connected to assignment due dates and instructor notifications with the MindTap Mobile app...

*and most of all...*EARN BETTER GRADES.

Contents

Preface xvii
About the Authors xxiii

1 The Development Through Life Perspective 3

CASE STUDY Ruth Hamilton 4

Assumptions of the Text 5

A Psychosocial Approach: The Interaction of the Biological, Psychological, and Societal Systems 6

- The Biological System 6
- The Psychological System 7
  - Meaning Making 7
- The Societal System 8
  - The Psychosocial Impact of Poverty 9

APPLYING THEORY AND RESEARCH TO LIFE: Poverty 10

- Overview of the Psychosocial Approach 11

CASE STUDY Rose 12

The Life Span 13

- Life Expectancy 13
  - Group Differences in Life Expectancy 14
- Factors That Contribute to Longevity 15
  - Education 15
  - Social Integration 15
  - Diet 16
  - Exercise 16

Chapter Summary 16

2 Major Theories for Understanding Human Development 19

CASE STUDY Jack Manasky and His Daughter Marilyn 20

What Is a Theory? 20

- Requirements of a Theory 21
- Requirements for Theories of Development 22

The Theory of Evolution 23

- Ethology 23
- Evolutionary Psychology 24
- Implications for Human Development 25
- Links to the Psychosocial Approach 25

Psychoanalytic Theory 26

- Five Components of Psychoanalytic Theory 26
  - Motivation and Behavior 26
  - Domains of Consciousness 26
  - Three Structures of Personality 27
  - Stages of Development 28
  - Defense Mechanisms 28
- Object Relations Theory 29
- Ego Psychology 30
- Implications for Human Development 30
- Links to the Psychosocial Approach 31

Cognitive Developmental Theories 32

- Basic Concepts in Piaget's Theory 32
  - Stages of Development 32
- Implications of Piaget's Theory for Human Development 33
- Vygotsky's Concepts of Cognitive Development 34
  - Lower and Higher Mental Processes 34
  - Culture as a Mediator of Cognitive Structuring 34
  - Movement from Intermental to Intramental 35
  - Inner Speech 35
  - The Zone of Proximal Development 35
- Implications of Vygotsky's Theory for Human Development 35
- Links to the Psychosocial Approach 36

Theories of Learning 37

- Social Learning Theory 37
- Implications of Social Learning Theory for Human Development 38
- Cognitive Behaviorism 38

APPLYING THEORY AND RESEARCH TO LIFE: Cognitive Behavioral Therapy 39

- Implications of Cognitive Behaviorism for Human Development 39
- Links to the Psychosocial Approach 40

Cultural Theory 40
- Cultural Continuity and Discontinuity 41
- Individualism and Collectivism 41

HUMAN DEVELOPMENT AND DIVERSITY: Implications of Individualism and Collectivism for Parenting Practices: 42
- Implications for Human Development 43
- Links to the Psychosocial Approach 43

Social Role Theory 44
- Implications for Human Development 44

APPLYING THEORY AND RESEARCH TO LIFE: Role Strain and Parenthood 45
- Links to the Psychosocial Approach 46

Systems Theory 47
- Characteristics of Open Systems 47
- Ecological Systems Theory 47
- Implications for Human Development 49
- A Systems View of Families 49
- Links to the Psychosocial Approach 50

Chapter Summary 51

3 Psychosocial Theory 55

The Rationale for Emphasizing Psychosocial Theory 56

CASE STUDY Erik H. Erikson 57

Basic Concepts of Psychosocial Theory 57
- Stages of Development 60
- Developmental Tasks 62
- Psychosocial Crisis 64
  - Psychosocial Crises of the Life Stages 65
  - Unforeseen Crises 65

APPLYING THEORY AND RESEARCH TO LIFE: Using Autobiographical Memories to Explore Psychosocial Stages of Life 66
- The Central Process for Resolving the Psychosocial Crisis 67
- Radius of Significant Relationships 68
  - Contexts of Development 69
- Coping 70
  - Prime Adaptive Ego Qualities 72
  - Core Pathologies 72

Evaluation of Psychosocial Theory 73
- Strengths 73
- Weaknesses 74
- A Recap of Psychosocial Theory 76

Chapter Summary 77

4 The Period of Pregnancy and Prenatal Development 81

CASE STUDY Experiencing Pregnancy 82

Genetics and Development 82
- Chromosomes and Genes as Sources of Genetic Information 82
- The Principles of Heredity 83
  - Alleles 84
  - Genotype and Phenotype 84
  - Epigenetics 84
  - Sex-Linked Characteristics 86
- Genetic Sources of Individual Differences 86
  - Mutations 86
  - Genetic Determinants of the Rate and Sequence of Development 87
  - Genetic Determinants of Individual Traits 87
  - Genetic Determinants of Abnormal Development 88
- Genetic Technology and Psychosocial Evolution 89
  - Ethical Considerations 89
- Gene X Environment Interactions and Behavior 90
  - Genetics and Intelligence 90
  - The Norm of Reaction 91

Normal Fetal Development 92
- Fertilization 92
  - Twins 93
- Infertility and Alternative Means of Reproduction 93
  - Ethical Considerations of ART 94

APPLYING THEORY AND RESEARCH TO LIFE: Reproductive Technologies 95
- Adoption 96
- Development in the First Trimester 97
  - The Germinal Period 97
  - The Embryonic Period 97
  - The Fetal Period 99
- Development in the Second Trimester 100
- Development in the Third Trimester 101
  - Advantages of a Full-Term Fetus 101

The Birth Process 102
- Stages of Labor 102
- Cesarean Delivery 102
- Infant Mortality 102

The Mother, the Fetus, and the Psychosocial Environment 103
- The Impact of the Fetus on the Pregnant Woman 103
  - Changes in Roles and Social Status 103
  - Being Pregnant Changes a Woman's Emotional State 104
  - **APPLYING THEORY AND RESEARCH TO LIFE: The Doula or Birth Companion** 105
  - Fathers' Involvement During Pregnancy 105
  - Fathers' Involvement in Labor and Delivery 107

CASE STUDY A Father's Recollections About His Daughter's Birth 107
- The Impact of the Pregnant Woman on the Fetus 108
  - The Impact of Poverty 108
  - Mother's Age 108
  - Maternal Drug Use 109
  - Environmental Toxins 112
  - Mother's Diet 112
  - Stress and Fetal Development 113
  - Summary 114

The Cultural Context of Pregnancy and Childbirth 115
- Reactions to Pregnancy 115
- Solicitude Versus Shame 115

HUMAN DEVELOPMENT AND DIVERSITY: Couvade 116
- Adequacy Versus Vulnerability 116
- Reactions to Childbirth 117

Applied Topic: Abortion 120
- What Is Abortion? 120
- The Legal and Political Context of Abortion in the United States 120
- Statistics About Legal Abortions and the Women Who Have Them 122
- The Psychosocial Impact of Abortion 122

CASE STUDY Karen and Don 123
- Men's Reactions to Abortion 124

Chapter Summary 125

5 Infancy (First 24 Months) 129

CASE STUDY A Close Look at a Mother–Infant Interaction 130

Newborns 131

APPLYING THEORY AND RESEARCH TO LIFE: Very Small Babies 132

Developmental Tasks 133
- The Development of Sensory/Perceptual and Motor Functions 133
  - Brain Development in Infancy 133

APPLYING THEORY AND RESEARCH TO LIFE: The Impact of Early Life Stress on Subsequent Brain Development 135
  - Sensory/Perceptual Development 136
  - The Interconnected Nature of Sensory/Perceptual Capacities 139
  - Motor Development 140
  - Motor Milestones 141
  - The Contributions of Nature and Nurture in Motor Development 142

APPLYING THEORY AND RESEARCH TO LIFE: The Dynamic Development of Stepping 143
- Sensorimotor Intelligence: Processing, Organizing, and Using Information 144
  - Information-Processing Abilities 144
  - Causal Schemes 145
  - Understanding the Nature of Objects and Creating Categories 146
  - The Prefrontal Cortex and Infant Intelligence 148
- Communication 148
  - Language Perception 149
  - Babbling 149
  - Communication with Gestures 149
  - Early Grammar Recognition 150
  - First Words 151
- Attachment 151
  - The Development of Attachment 152
  - Stranger Anxiety 153
  - Separation Anxiety 153
  - Formation of Attachments with Mother, Father, and Others 154
  - Patterns of Attachment 154
  - Parental Sensitivity and the Quality of Attachment 155

APPLYING THEORY AND RESEARCH TO LIFE: Is There a Sensitive Period for Attachment? 156
  - The Relevance of Attachment to Subsequent Development 158

APPLYING THEORY AND RESEARCH TO LIFE: The Neuroscience of Attachment 159
  - Critique of the Attachment Paradigm 160
- Emotional Development 161
  - Emotional Differentiation 161

    Emotions as a Key to Understanding Meaning 163
    The Ability to Regulate Emotions 163
CASE STUDY The Cotton Family 165
    Emotions as a Channel for Adult-Infant Communication 166

The Psychosocial Crisis: Trust Versus Mistrust 168
  Trust 168
  Mistrust 168

The Central Process for Resolving the Crisis: Mutuality with the Caregiver 169
  Coordination, Mismatch, and Repair of Interactions 170
  Establishing a Functional Rhythm in the Family 171
  Parents with Psychological Problems 171

The Prime Adaptive Ego Quality and the Core Pathology 171
  Hope 171
  Withdrawal 172

Applied Topic: The Role of Parents 172
  Safety and Nutrition 173
    Safety 173
HUMAN DEVELOPMENT AND DIVERSITY: Sensitive Care in Two Cultures 174
    Nutrition 175
  Fostering Socioemotional and Cognitive Development 175
  Fathers' and Mothers' Parental Behaviors 176
  Parents as Advocates 178
  The Importance of Social Support 178

Chapter Summary 179

6 Toddlerhood (Ages 2 to 4 Years) 183

CASE STUDY Harrison Struggles in the Transition to Preschool 184

Developmental Tasks 184
  Elaboration of Locomotion 185
    Locomotion and Cognition 185
    Dynamic Systems Theory and Locomotion 185
    Landmarks of Motor Development 185
    Locomotion and Play 186
    Motor Impairments 187
  Language Development 187
APPLYING THEORY AND RESEARCH TO LIFE: How the Brain Processes Language 188
    Communicative Competence 189
    Language Milestones in Toddlerhood 189
    The Language Environment 193
HUMAN DEVELOPMENT AND DIVERSITY: Bilingualism 195
  Fantasy Play 199
    The Nature of Pretend Play 199
    The Capacity for Pretense 199
    How Fantasy Play Changes During Toddlerhood 200
    Theoretical Views about the Contributions of Fantasy Play to Development 201
    The Role of Play Companions 202
APPLYING THEORY AND RESEARCH TO LIFE: Imaginary Companions 203
  Self-Control 204
    Control of Impulses 204
APPLYING THEORY AND RESEARCH TO LIFE: The Expression and Control of Angry Feelings 205
    Increasing Sensitivity to the Distress of Others 206
    Self-Directed Goal Attainment 210

The Psychosocial Crisis: Autonomy Versus Shame and Doubt 211
  Autonomy 212
  Shame and Doubt 213

The Central Process: Imitation 213
HUMAN DEVELOPMENT AND DIVERSITY: Toilet Training 214

The Prime Adaptive Ego Quality and the Core Pathology 215
  Will 216
  Compulsion 216

The Impact of Poverty on Psychosocial Development in Toddlerhood 217
  Poverty and Brain Development 217
  Poverty and Health 217
HUMAN DEVELOPMENT AND DIVERSITY: Autism Spectrum Disorder 218
  Poverty Impacts the Parenting Environment 219
  Poverty and Academic Outcomes 219
  Poverty Worldwide 219

Applied Topic: Child Care 220
  The Impact of Child Care on Intelligence, Cognition, and Academic Achievement 221
  The Impact of Child Care on Social Competence 222
  Child Care and Physical Activity 223
  Benefits Associated with Head Start 224
  Directions for the Future of Child Care in the United States 224

Chapter Summary 225

7 Early School Age (4 to 6 Years) 229

CASE STUDY Gloria Remembers Being 5 Years Old 230

Developmental Tasks 230
- Gender Identification 231
- **CASE STUDY** Gender Identification in Early Childhood 231
  - A Framework for Thinking About Gender Identification 232
  - Understanding Gender 233
  - Gender-Role Standards and Sex Stereotypes 234
  - Identification with Parents 235
  - Gender Preference 235

APPLYING THEORY AND RESEARCH TO LIFE: Children Raised by LGBT Parents 236
- Early Moral Development 238
  - Internalization 239
  - Five Theoretical Perspectives on Moral Development 239
- **CASE STUDY** Early Learning About Obedience 243
  - Empathy, Caring, and Perspective Taking 244
  - Parental Discipline 245
  - The Impact of Media, Including Television and Video Games, on Moral Development 246
  - Review of Influences on Moral Development 248
- Self-Theory 250
  - The Neuroscience of the Self 250
  - The Me and the I 251
  - Developmental Changes in the Self-Theory 251
  - Culture and the Self-Theory 252
  - Self-Esteem 253
- Peer Play 255
  - Group Games 255
  - Media Play 255
  - Income Inequality and Media Access 256
  - Friendship Groups 257

The Psychosocial Crisis: Initiative Versus Guilt 259
- Initiative 259
- Guilt 260

The Central Process: Identification 262

The Prime Adaptive Ego Quality and the Core Pathology 263
- Purpose 263
- Inhibition 264

Applied Topic School Readiness 264
- What Do We Mean by Readiness? 265
- Measuring Kindergarten Readiness 265
- Risk Factors for School Readiness 266
- Who Is Responsible for Meeting the Goal for School Readiness? 267

HUMAN DEVELOPMENT AND DIVERSITY: Supporting School Readiness for Young Children with Disabilities 268

Chapter Summary 268

8 Middle Childhood (6 to 12 Years) 271

CASE STUDY Recollections of Childhood Friends 272

Developmental Tasks 273
- Friendship 273
  - Family Influences on Social Competence 273
  - Three Contributions of Friendship to Social Development 275
  - Loneliness 277
  - Rejection 279

APPLYING THEORY AND RESEARCH TO LIFE: Bullying 280
- Concrete Operations 281
  - Conservation 282
  - Classification Skills 284
  - Computational Skills 285
  - Metacognition 286
- Skill Learning 287
  - Features of Skilled Learning 288
  - Principles of Skill Development 288

APPLYING THEORY AND RESEARCH TO LIFE: What Is Intelligence? 289
  - Early Deprivation and Skill Development 290
  - Reading 291

HUMAN DEVELOPMENT AND DIVERSITY: Cross-national Comparisons of Mathematics Ability 292
- Self-Evaluation 294
  - Feelings of Pride 295
  - Self-Efficacy 295
- **CASE STUDY** Becca 296
  - Social Expectations 297
  - Illusions of Incompetence and Competence 298
- Team Play 300
  - Health and Fitness 300
  - Interdependence 301
  - Division of Labor 301
  - Competition 301

Cooperation 302
In-Group and Out-Group Attitudes 302
Team Play as a Context for Development 303

The Psychosocial Crisis: Industry Versus Inferiority 304

Industry 304
Inferiority 305

HUMAN DEVELOPMENT AND DIVERSITY: Disabilities of Childhood and School Success 306

The Central Process: Education 308

The Prime Adaptive Ego Quality and the Core Pathology 310

Competence 310
Inertia 310

Applied Topic: Violence in the Lives of Children 311

Consequences of Exposure to Violence 311
- Children as Victims of Violence 311
- Exposure to Violence and Aggressive Behaviors 312
- Exposure to Violence Disrupts Cognitive and Emotional Development 312

Preventing Violence 312

Chapter Summary 313

9 Early Adolescence (12 to 18 Years) 317

CASE STUDY Evelyn Cabrera: Balancing Autonomy and Closeness in Early Adolescence 318

Developmental Tasks 319

Physical Maturation 319

APPLYING THEORY AND RESEARCH TO LIFE: Sleep Loss in Adolescence 320

CASE STUDY Simone Biles: Three Time World All-Around Gymnastics Champion 321

- Signposts of Puberty for Girls 321
- Reactions to Breast Development and Menarche 322
- Concerns About Obesity 322
- Signposts of Puberty for Boys 323
- Boys' Reactions to the Physical Changes of Puberty 323
- Cultural Contexts of Puberty 324
- The Secular Growth Trend 325
- Individual Differences in the Timing and Rate of Change 325

Romantic and Sexual Relationships 327
- The Transition into Sexualized Relationships 327
- Factors Affecting the Initiation of Sexual Intercourse 329
- The Effects of Religious Beliefs on Sexual Behavior 330
- Sexual Orientation 330
- Transgender Youth 333
- Problems and Conflicts Associated with Sexuality 333
- Parenthood in Early Adolescence 336

Formal Operations 338
- Brain Development in Adolescence 338
- Piaget's Theory of Formal Operational Thought 339
- Six Characteristics of Formal Operational Thought 340
- Factors That Promote Formal Operational Thought 340
- Criticisms of the Concept of Formal Operational Thought 342

Emotional Development 343
- The Neuroscience of Emotion and Cognition 344
- The Diversity of Emotions in Adolescence 345
- Internalizing and Externalizing Problems 346

APPLYING THEORY AND RESEARCH TO LIFE: Adolescent Suicide 350

Membership in the Peer Group 352
- Cliques and Crowds 353
- Group Boundaries and Norms 354
- Parents and Peers 355

The Psychosocial Crisis: Group Identity Versus Alienation 356

Group Identity 356
- Cognitive Processes That Support the Formation of Group Identity 357
- Four Types of Experiences That Build a Group Identity 358
- Ethnic Group Identity 359

Alienation 360
- The Contribution of Alienation to Group Identity and Individual Identity 361

The Central Process: Peer Pressure 362

Affiliating with a Peer Group 363
Conflicts Between Belonging and Personal Autonomy 363

The Prime Adaptive Ego Quality and the Core Pathology 363

Fidelity to Others 363

APPLYING THEORY AND RESEARCH TO LIFE: Youth Gangs 364

Dissociation 365

Applied Topic: Adolescent Alcohol and Drug Use 366
- Physical Effects of Alcohol 367
- Factors Associated with Alcohol Use 367
  - Cognitive Factors 367
  - Motivation and Emotion 367
  - The Social Contexts of Alcohol Use 368

Chapter Summary 368

10 Later Adolescence (18 to 24 Years) 373

CASE STUDY Growing Up Through Divorce: A College Student's Insights 374

Developmental Tasks 375
- Autonomy from Parents 375
  - Autonomy and Leaving Home 377
  - Autonomy and the College Experience 377
  - Revision of Attachment to Parents 378
  - Autonomy and Self-Sufficiency 379

APPLYING THEORY AND RESEARCH TO LIFE: Attachment and Identity Formation 380
- Gender Identity 381
  - The Role of Culture 382

HUMAN DEVELOPMENT AND DIVERSITY: Third Genders 383
  - Reevaluating Gender Constancy 384
  - Reevaluating Earlier Gender-Role Standards and Learning New Ones 384
  - Revising Childhood Identifications 385
  - Adding a Sexual Dimension to Gender Identity 385
  - Integrating One's Gender Identity 387
- Internalized Morality 388
  - New Cognitive Capacities 388
  - Stages of Moral Reasoning 389
  - Experiences That Promote Moral Reasoning 389
  - A Maturing Moral Identity 390
- Career Choice 392
  - Work Experiences in Early Adolescence 392
  - Factors Influencing Career Choice 392
  - Career Decision Making 395
  - Career Decision-Making Self-Efficacy 397
  - The Impact of the Labor Market on Career Decision Making 398

The Psychosocial Crisis: Individual Identity Versus Identity Confusion 399
- Individual Identity 399
  - The Private and Public Faces of Identity 399
  - The Content and Evaluation Components of Identity 400

CASE STUDY Houston A. Baker, Jr. 400
  - Identity Status 401
- Identity Confusion 402
  - Developmental Progression 403
  - Identity Formation for Men and Women 403

The Central Process: Role Experimentation 404
- Psychosocial Moratorium 404
- Individual Differences in Role Experimentation 405

CASE STUDY Turning Points in the Identity Process 406
- Role Experimentation and Ethnic Identity 406

HUMAN DEVELOPMENT AND DIVERSITY: Ethnic Identity and Adjustment 408

The Prime Adaptive Ego Quality and the Core Pathology 408
- Fidelity to Values and Ideologies 409
- Repudiation 409

Applied Topic: Dropping Out of College 409
- Financial Factors 410
- Academic Preparation 410
- Personal Factors 410
- Characteristics of the College Environment 412
- The Consequences of Dropping Out of College 412

Chapter Summary 413

11 Early Adulthood (24 to 34 Years) 417

CASE STUDY Changing Work to Recapture Love and Happiness 418

Expanding Theoretical Views of Adult Development 418
- Social Roles 419
- Life Course 420
- Fulfillment Theories 422
  - Competence 422
  - Self-Acceptance 422
  - Self-Actualization 422

Developmental Tasks 424
- Exploring Intimate Relationships 425
  - Readiness to Form Intimate Relationships 425
  - Readiness to Marry 426
  - Phases in the Selection of a Partner 426

CASE STUDY Hannah and Matt: An Online Dating Couple's Story 428

APPLYING THEORY AND RESEARCH TO LIFE: Attachment Styles and Relationship Formation 430
  - Cohabitation 432
  - Close Relationships Between Partners of the Same Sex 433
  - Adjustment During the Early Years of Marriage 435
- Childbearing 438
  - Fertility Rate 439
  - Decisions About Childbearing 439

HUMAN DEVELOPMENT AND DIVERSITY: The Reproductive Career of the Gusii 440
  - Adjustment During Pregnancy and Childbearing 442
  - The Dual Roles of Intimate Partner and Parent 442
  - Nonmarital Childbearing 443
  - Adoption 443
  - The Decision Not to Have Children 444
- Work 445
  - The World of Work 445
  - Poverty and Career Opportunities 449
  - Career Phases and Individual Development 449
- Lifestyle 449
  - Pace of Life 451
  - Social Network 451
  - Striving for Work/Life Balance 452
  - Health, Fitness, and Nutrition 453

Preface

The first edition of *Development Through Life* was published in 1975. Since that time, an expanding scientific study of human development and increases in longevity have converged to create a remarkable revision of our understanding of the life course. Insights about human development have emerged in a vibrant research environment with new interdisciplinary approaches to research, greater inclusion of diverse samples in the United States and internationally, new statistical techniques to manage multiple observations and multiple variables, and a growing acceptance of qualitative studies.

Today, the years of infancy and childhood comprise a smaller percentage of the life span than was the case in 1975. Researchers look in much greater detail at the prenatal stage as a dynamic period when learning begins, the environment impacts the developmental trajectory, and conditions of pregnancy influence fetal growth. Genetic studies now recognize the role of the environment in silencing or enhancing gene expression in ways that can be transmitted from one generation to the next. Research on infant development, particularly in the first days and weeks of life, has flourished, resulting in greater appreciation for the cognitive and sensory capacities of the newborn. The expanding field of evolutionary psychology has shed new light on the adaptive capacities of infants and the features of the parent-infant relationships that contribute to survival and long-term growth. There is a growing consensus about what constitutes effective or "good" parenting and the cascading negative impact of harsh or neglectful parenting.

The application of developmental systems theory has provided many new insights into the way change occurs. We view development as a product of the interaction of many levels at once, each potentially altering the others. For example, neuroimaging studies illustrate how various areas of the brain interact and influence each other. As a person engages in cognitive tasks, such as problem solving or risk assessment, areas of the brain involved in emotion regulation, attention, motor activity, and sensory processing are all recruited.

In the current edition of *Development Through Life*, we have included discussions about conditions of life in other industrialized countries. We are troubled to note many ways in which life in the United States, as exciting and promising as it is, does not compare favorably. As you read, you will find that infant mortality, student performance in math and science, teen pregnancies, school dropouts, children and adolescents who are victims of violent crime, children in poverty, children who experience multiple parental transitions, debt-burden in later adolescence and early adulthood, homelessness, and the health and longevity of the elderly are all less favorable in the United States than in many other countries. These comparisons lead us to urge scholars in human development to be more active advocates for policies that promote optimal development through the life span.

One of the troubling realities of the current historical period is extreme income inequality in the United States and associated disparities in health, educational attainment, and occupational opportunities. Despite the knowledge about effective interventions and best practices, greed among the very top segment of the population is preventing the level of investment in programs that would improve many of the conditions mentioned above. From a psychosocial perspective, we see evidence of stagnation among the very wealthy that has serious implications for future societal well-being.

The Stage Approach

The text provides a thorough chronological introduction to the study of human development from conception through elderhood. We examine physical, intellectual, social, and emotional growth in each of 11 stages, emphasizing that development results from the interdependence of these areas at every stage. This strategy gives attention to important developmental themes that recur in different stages of life. For each life stage, the process of development is linked to internal conflicts, changing self-awareness, and a dynamic social environment. As a result, students gain a sense of a multidimensional person, striving toward new levels of competence and mastery, embedded in multiple contexts.

In our stage approach, we cover two stages of adolescence, early adolescence with the psychosocial crisis of group identity versus alienation, and later adolescence, with the psychosocial crisis of individual identity versus identity confusion. We are witnessing an ever more gradual transition out of adolescence into adulthood so that the period we call later adolescence is lasting well into the decade of the 20s. Research on educational and occupational attainment, relationships with family, and the formation of intimate bonds all point to the idea that the life commitments that used to be formed in the decade of the 20s are being forestalled for many young people into their late 20s and 30s. Studies of brain development lend support to this view of a more gradual transition from adolescence to adulthood as capacities for executive function become increasingly coordinated with other brain regions governing emotional reactions and responses to stress.

Life expectancy in the United States has changed over the past 40 years so that today those who are already age 65 can expect to live an average of another 19 years. As a result, we cover two stages of later life: later adulthood and elderhood. Those in the period of elderhood (ages 75 and beyond) are the fastest-growing segment of the U.S. population. As the baby boomers age, they will contribute to an even greater proportion of the population in elderhood. These elders will experience a period of life that is more active, more informed about healthy lifestyle practices, and less constrained by traditional gender and family role scripts than ever before. At the same time, a burst in commercialism is targeting older adults and making them potentially vulnerable to exploitation and poor quality care.

Advantages of the Psychosocial Framework

Psychosocial theory provides an organizing conceptual framework, highlighting the continuous interaction and integration of individual competencies with the demands and resources of culture. Development is viewed as a product of genetic, maturational, societal, and self-directed factors. The psychosocial framework helps students think about how people make meaning of their experiences and how efforts at meaning making change over the life span. Applying the psychosocial framework to an analysis of human development has the following advantages:

- Helps to identify and emphasize themes and directions of growth across the life span.
- Helps readers assess the influence of experiences during earlier life stages on later development.
- Clarifies how one's past, present, and expectations of the future are systematically connected to the lives of people who are older and younger, highlighting intergenerational transmission and the reciprocal influences of the generations.
- Offers a hopeful outlook on the total life course, including positive psychological capacities such as hope, purpose, love, and caring.
- Offers insight into human vulnerabilities at each life stage, embracing these negative poles as potentially adaptive while recognizing the possibility that they can result in an outlook of extreme cautiousness, self-doubt, or social withdrawal.
- Clarifies how a personal worldview develops within the context of cultural influences and historical events.
- Locates development within a framework of significant relationships, emphasizing the simultaneous and complementary processes of autonomy and connection.

The Life-Span Perspective

When we wrote the first edition of *Development Through Life*, we had just completed graduate study, had two young children, and were in the midst of early adulthood. Now, at the publication of the 13th edition, we have just celebrated the birth of our fifth grandchild; our three adult children are all married, living in cities across the country and thriving in their careers; and we are experiencing the challenges of later adulthood.

The psychosocial life-span perspective has been a valuable orienting framework for our scholarly work as well as our personal lives. It has provided insights into the birth and parenting of our children and grandchildren; the deaths of our parents; the successes, disappointments, and transitions of our work lives; and the conflicts and delights of our relationship as husband and wife. The themes of this book have allowed us to anticipate and cope with the challenges of adult life and to remain resilient in the face of crises. We hope that the ideas presented in this text will provide these same benefits to you.

In addition to enhancing self-understanding, the life-span perspective provides a broader worldview. The ego strengths and developmental competences of those in early, middle and later adulthood provide the resources that are needed to care for and nurture the young. The way that elders find meaning in their longevity and approach the end of life inspire those in younger stages to live their life with hopefulness. And now, in the context of rapidly changing electronic media, younger children and adolescents are increasingly able to guide their elders in embracing new technologies. The life-span perspective helps steer interactions with others so they can be optimally sensitive, supportive, and facilitative for growth at each life stage.

Effects of Cultural and Historical Contexts

The developing person exists in a changing cultural and historical context. Studying development over the course of life requires awareness of the ways societies change over time. The population of the U.S. has increased from 216 million in 1975 to 324 million in 2016. The diversity of this population has changed as well. For example, in 1970 4% of the population was Hispanic; today 16% are Hispanic. Life expectancy in the U.S. in 1970 was 69 for men, 77 for women; in 2010 this had increased to 76 for men and 81 for women. People are waiting longer to marry, family size has decreased, and more adults are voluntarily childless, resulting in an aging population. In this context, people like to say "60 is the new 40." For the field of human development this means that we have to revise our ideas about chronological age and expectations for behavior.

In 1975 there were no cell phones, no desk top computers in the home, and, of course, no email, texting, Facebook, or Twitter. Cell phones are now tiny hand-held computers that dramatically alter the way we connect with one another, entertain ourselves, and gather information. With every kind of streaming resource, people can create their own electronic environment and take it with them, making the notion of "environment" highly personalized.

And amid this swirling technological change, where robots are taking on many of the tasks that used to be done by human hands, the world of work is in flux, and social values are also changing. Dual earner couples are the norm, the boundary between home and work is extremely permeable, there is a great diversity of family structures, more acceptance of lifestyle choices, and fewer constraints about gender roles and sexuality. The task of tracing patterns and pathways of development over the lifespan is becoming increasingly challenging.

Effects of Poverty, Discrimination, and Other Forms of Societal Oppression

The National Center for Children in Poverty at Columbia University estimates that a family of four actually needs twice the income of the poverty level, which was $24,250 a year in 2015, to cover basic expenses. Using this statistic, the Center estimates that 45% of children live in low-income families. The impact of poverty cascades through life from increased risks during the prenatal period through disruptions in physical, cognitive, and emotional development in infancy, childhood, adolescence, and into adult life.

As income inequality increases and scientific evidence about the impact of poverty on health, educational attainment, employment, housing, and longevity accumulates, a number of nongovernmental groups are taking independent actions to form coalitions, raise awareness, and create local programs to deliver services and support the well-being of low-resource families.

Numerous examples of the ways that poverty, discrimination, and various forms of societal oppression affect individual development are interwoven throughout the text. At the same time, research on resilience illustrates the remarkable capacities for growth and adaptation at every period of life.

Organization

Guided by psychosocial theory, we return again and again to the ideas that human development is a social enterprise, that meaning making emerges in social and cultural contexts, and that individuals play a role in shaping the direction of their development. We use case material, boxes on diversity, international data, and cultural examples to emphasize these themes. The following summarizes the basic organization of the text.

Introducing the Field: Chapters 1 to 3

Chapter 1 describes the orientation and assumptions of the text, introduces the psychosocial life-span perspective, and introduces data about longevity and life expectancy, setting the stage for the idea that the lifespan unfolds in a changing historical context. Chapter 2 introduces the role of theory in human development and the questions that a theory of human development is expected to address. The chapter outlines significant ideas about change and growth from seven theoretical perspectives. The presentation of each theory emphasizes its basic features, implications for the study of human development, and links to the psychosocial framework. Chapter 3 introduces basic concepts of psychosocial theory, including an analysis of its strengths and weaknesses.

The Latest on Pregnancy and Prenatal Development: Chapter 4

In Chapter 4, fetal development is presented, highlighting the bidirectional influences of the fetus and the pregnant woman within her social and cultural environments. Continuing discoveries in the field of behavioral genetics have been included in this revision. The chapter traces changes in physical and sensory development across the three trimesters. The chapter covers issues of infertility, alternative reproductive techniques, and ethical considerations surrounding their implementation. We have emphasized research on the health and well-being of pregnant women and their partners, as well as risks to fetal development associated with a pregnant woman's exposure to a wide range of substances, especially nicotine, alcohol, caffeine, other drugs, and environmental toxins. Poverty is discussed as a context that increases risks for suboptimal development. This chapter includes a detailed description of cultural differences in the way pregnancy and childbirth are conceptualized, providing a model for considering the psychosocial process as it will unfold in subsequent chapters. The applied topic of this chapter is abortion; an issue that clearly illustrates the relevance of the field of human development for salient personal, social and cultural perspectives.

Growth and Development from Infancy to Elderhood: Chapters 5 to 14

Chapters 5 through 14 trace basic patterns of normal growth and development in infancy, toddlerhood, early school age, middle childhood, early adolescence, later adolescence, early adulthood, middle adulthood, later adulthood, and elderhood. In these chapters we consider how individuals organize and interpret their experience, noting changes in their behavior, attitudes, worldview, and the coping strategies they use in the face of changing environmental demands.

Each chapter begins with an examination of four or five of the critical developmental tasks of the stage. These tasks reflect global aspects of development, including physical maturation, sensory and motor competence, cognitive maturation, emotional development, social relationships, and self-understanding. We consider the psychosocial crisis of each stage in some detail. We also show how successfully resolving a crisis helps individuals develop a prime adaptive ego quality and how unsuccessful resolution leads to a core pathology. Although most people grow developmentally—albeit with pain and struggle—others do not. People who acquire prime adaptive ego qualities are more likely to lead active, flexible, agentic lives, and be resilient in the face of stressors. People who acquire core pathologies are more likely to lead withdrawn, guarded lives; they are more vulnerable to stressors resulting in greater risk of mental and physical health problems.

Applied Topics at the End of Each Chapter

We conclude each chapter by applying research and theory to a topic of societal importance. These applied topics provide an opportunity for students to link the research and theory about normative developmental processes to the analysis of pressing social concerns. Table 3.1 contains an overview of the basic tasks, crises, and applied topics for each stage of life.

Understanding Death, Dying, and Bereavement: Chapter 15

Chapter 15 addresses end-of-life issues within a psychosocial framework. As with the developmental stage chapters, the topic illustrates the interaction of the biological, psychological, and societal systems as they contribute to the experiences of dying, grieving, and bereavement. The chapter includes definitions of death, the process of dying, death-related rituals, grief, and bereavement, including a focus on the role of culture in shaping ideas about death and expressions of grief. The chapter ends with a discussion of the opportunities for psychosocial growth that are a result of bereavement and the considerations of one's own mortality.

Research Appendix

The Research Appendix highlights basic principles of the scientific process, including the positivist and qualitative approaches to inquiry. The Appendix reviews basic topics in research design including sampling, research methods, and designs for studying development. A section on evaluating research highlights the need to approach the results of research as a critical and informed consumer, recognizing some of the limitations and biases that may be imbedded in the research process. Finally, we review ethical guidelines for conducting research with human participants.

New to This Edition

The 13th edition has retained the basic structure and positive developmental emphasis of previous editions. We continue to strive to make the text clear, readable, and thought provoking, while capturing the complexities and novel concepts that make the study of human development so fascinating. In this edition, each chapter begins with case material that helps bring important themes from the chapter into focus. References to these introductory cases are spread throughout the chapter, providing opportunities to apply concepts to real-world examples. In addition, new first-person quotations have been incorporated to highlight the process of meaning-making that takes place as individuals face the developmental challenges of their stage of life.

The chapters have been rewritten with an effort to streamline and reorganize the material to ensure a clearer and more focused discussion. The text has been completely updated. New research findings, recent census data, updated results of ongoing studies that collect data on new cohorts, and results of ongoing longitudinal studies have been integrated into the narrative. The results of studies using large data sets are summarized as well as some discussion about the difficulties associated with these studies.

The 13th edition is published in a vibrant, new 4-color format. The Picasso paintings, which have been so intimately woven into earlier editions, are now in full color. We hope these wondrous works help students see the connection between the creative enterprise in art, with its experimentation, whimsy, innovation, and insight, and the imaginative, playful and innovative forces at work in creating a life. The 4-color format also improves readability, bringing increased attention to features such as section headings, tables, figures, photographs, and boxes.

On the advice of reviewers, three contemporary research themes have been expanded in this edition: 1. developmental neuroscience; 2. health, fitness, and disability; and 3. the impact of the electronic media environment. Research findings, boxes, tables, and case material have been introduced to extend coverage of these themes across the lifespan. Some examples of these additions are listed below:

Updates on risks associated with prescription drugs during pregnancy.

New information on food safety and nutrition during pregnancy.

New approaches and data on outcomes of assisted reproductive technologies.

Mental health stressors and possible psychological reactions to childbirth for new immigrants highlighting the interaction of culture with mental and physical health.

A box on the neuroscience of attachment.

The dynamic interaction of neurological structures and systems in the coordination of decision-making, risk assessment, and responses to stress.

Robbie Case's theory of Central Conceptual Structures, which integrates cognitive neuroscience and information processing with a constructivist approach to cognitive development.

The impact of poverty on health, including the long-term consequences of early childhood poverty on adult health.

The impact of harsh and neglectful parenting on brain development.

The nature of autism spectrum disorder and its treatment in toddlerhood.

The nature and prevalence of electronic media use in infancy, toddlerhood, early childhood and adolescence.

New insights about sexuality and gender in childhood, adolescence, and adulthood.

Research on transgender issues in childhood, adolescence, and adulthood.

Update on the impact of media on moral development in early school age.

Data on the percent of young children who engage in various types of daily media activities.

The nature and impact of cyber bullying.

Disability and gender atypicality as factors that make children targets of bullying.

The use of computer-assisted match-making and dating sites in adolescence and early adulthood.

Issues faced by new immigrants, especially concerns with family stability, academic success, and physical and mental health.

Added cross-cultural research that highlights social relationships, parenting practices, academic achievement, the role of the elderly, and approaches to death, dying, and bereavement.

The impact of disability on career choice and employment.

The importance of exercise and its contribution to mental and physical health, life satisfaction, and cognitive capacities across the lifespan.

An evaluation of computer games on cognitive functioning in later adulthood.

The relationship of health, fitness, and disability to life acceptance and well-being in later adulthood.

Neuroplasticity, cognitive functioning, and aging.

The importance of nutrition, exercise, and fitness as aspects of lifestyle.

The role of neighborhood resources and design on exercise and fitness in later life.

Features That Support Learning

Several features are included in the 13th edition that we expect will contribute to the learning process.

1. **Organizational Chart:** There is a chart, Table 3.1, which provides a two-page overview of the organization of the text.
2. **Chapter Outlines:** A detailed outline of the chapters is provided at the beginning of the book. An outline is also presented at the start of each chapter.
3. **Chapter Learning Objectives:** Each chapter begins with Learning Objectives. These objectives have been stated using the six thinking processes: remember, understand, apply, analyze, evaluate, and create.

   These objectives are restated at the opening of each related section to help highlight the primary goal for that section of the text and are stated again in the chapter summary to help students review and integrate concepts from the chapter.
4. **Opening Case:** Each chapter starts with a case that brings to life one or more issues addressed in the chapter. These cases are followed by a set of questions labeled "Case Analysis: Using What You Know." The purpose of these cases is threefold: to help students become more personally attached to the concepts of the chapter; to provide a shared life experience that can serve as a basis for class discussion; and to encourage the application of concepts from the text and the course.
5. **Further Reflection:** At the end of each section within the chapter, one or more suggestions are labeled "Further Reflection." These are intended to prompt students to stop and think a bit about what they have just read. These suggestions and questions encourage students to engage in critical thinking, evaluate the information, and link the information to related concepts and/or to personal life experiences.
6. **Boxes:** Two types of boxes are included in the chapters: **Applying Theory and Research to Life** and **Human Development and Diversity**. At the end of each box, a series of critical thinking questions encourage students to evaluate and apply information. The boxes are intended to provide added detail to the text. In the boxes labeled **Applying Theory and Research to Life**, students are encouraged to see the relevance of human development theory and research to issues in contemporary life. In the boxes labeled **Human Development and Diversity**, topics that are covered in the text are expanded to illustrate how differences in culture, ethnicity, family structure, economic resources, and disability can influence developmental pathways.
7. **Case material:** Throughout the chapters longer cases and short vignettes complement the descriptions of developmental issues. These cases highlight the real-life experiences of individuals, sometimes illustrating how individuals cope with challenges at various points in life; and sometimes illustrating the diversity of experiences that are possible at a certain period of life.
8. **End of Chapter Summary:** The chapter summaries are organized around the learning objectives. These summary paragraphs are intended to remind the reader of the big ideas but do not replace a careful reading of the text.
9. **Key Terms:** Key terms are boldfaced in the text, typically defined within the text, and also defined in the glossary.
10. **Glossary:** A comprehensive glossary with brief definitions can be found at the end of the text.
11. **References:** A detailed list of references is provided including references to books, chapters, articles, and websites.
12. **Index:** There is both an author index and a subject index.

Acknowledgments

The works of Erik Erikson and Robert Havighurst have guided and inspired our own intellectual development. Their writings shaped the basic direction of psychosocial theory and have guided an enormous amount of research in human development. They directed us to look at the process of growth and change across the life span. They recognized the intimate interweaving of the individual's life story with a sociohistorical context, emphasizing societal pressures that call for new levels of functioning at each life stage. In their writing, they communicated an underlying optimism about each person's resilience, adaptability, and capacity for growth, an outlook that finds new expression in the work of positive psychology. At the same time, they wrote with a moral passion about our responsibility as teachers, therapists, parents, scholars, and citizens to create a caring society. We celebrate these ideas and continue their expression in the 13th edition of *Development Through Life*.

We want to acknowledge the hundreds of scholars upon whose work this revision is based. The science of human development is a growing, multidisciplinary field. Over the many editions of *Development Through Life*, we have been gratified to see the increasing use of basic concepts from the psychosocial perspective to inform the research agenda. Key constructs including developmental tasks, psychosocial crisis, the radius of significant relationships (social support), trust, autonomy, shame and guilt, industry, competence, group identity, personal identity, intimacy, isolation, generativity, integrity and wisdom have become cornerstones of the life-span perspective on development.

We want to express our thanks to our many students, colleagues, and friends who share their experiences and expertise. We are so appreciative of the faculty who continue to use this book; they are supportive of the psychosocial stage approach and let us know about the ways the book contributes to their students' learning. Through the years, our mentors, Bill McKeachie and Jim Kelly, were voices of wisdom, reminding us of the values of good scholarship and a generous heart. In the early part of our careers, a few friends stand out as people who encouraged us and trusted in our ability to forge this collaboration: Catherine Chilman, Margaret and Harold Feldman, Gisela Konopka, Anne McCreary Juhasz, and Freda Rebelsky. Our former students Brenda Lohman and Laura Landry Meyer were excellent collaborators on our life-span development case book. With each new edition, we turn to our children and their families to offer new observations, try out ideas, and talk over controversies. At each stage, they bring new talents and perspectives that enrich our efforts.

The 13th edition was produced under the guidance of our product manager Star Burruto and content developers Jasmin Tokatlian and Nedah Rose. Their advice, encouragement, support, and vision have been instrumental in bringing this edition to fruition. We are very lucky to have had the benefit of their creative energy. In addition, we would like to express our appreciation to the other professionals at Cengage who have helped make this book possible: Ruth Sataka-Corley, Content Production Manager; Vernon Boes, Art Director; and James Findlay, Marketing Manager.

Finally, we acknowledge the thoughtful, constructive comments and suggestions of the following reviewers: for this 13th edition, Diane Davis Ashe, Valencia College; Judy A. Daniels, University of Hawaii at Manoa; and Tracy A. Phillips. In earlier editions, we received feedback from Verneda Hamm Baugh, Kean University; Dianna G. Cooper, University of Indianapolis; Lisa C. Davies, Nashville State Community College; Tobi DeLong Hamilton, Lewis-Clark State College; Kalinda Jones, Saint Xavier University; Monica Miller-Smith, University of Connecticut-Stamford; Angel Brock Murphy, Eastern Gateway Community College; Alex Schwartz, Santa Monica College.

Supplements: Video and Electronic

Development Through Life: A Psychosocial Approach, 13th edition, is accompanied by supplementary resources prepared for both the instructor and student.

For the Instructor

Online PowerPoint® Slides

These vibrant Microsoft® PowerPoint® lecture slides for each chapter assist you with your lecture by providing concept coverage using images, figures, and tables directly from the textbook.

Online Instructor's Manual

This detailed manual provides sample syllabi, course guidelines, in-class exercises, and chapter objectives to assist instructors in teaching the course.

Cengage Learning Testing, powered by Cognero® Instant Access

Cengage Learning Testing Powered by Cognero® is a flexible, online system that allows you to: import, edit, and manipulate content from the text's test bank or elsewhere, including your own favorite test questions; create multiple test versions in an instant; and deliver tests from your LMS, your classroom, or wherever you want.

MindTap® Psychology, 1 term (6 months) Instant Access for Newman/Newman's Development Through Life: A Psychosocial

MindTap® Psychology for Newman/Newman's Development Through Life: A Psychosocial Approach, 13th Edition is the digital learning solution that powers students from memorization to mastery. It gives you complete control of your course—to provide engaging content, to challenge every individual, and to build their confidence. Empower students to accelerate their progress with MindTap. MindTap: Powered by You. MindTap propels students from memorization to mastery, beginning with Mastery Training as the first activity in each chapter. Investigate Development cases provide engaging real-life stories, with activities that ask students to summarize, analyze evidence, and apply what they have learned to reach conclusions. MindTap gives you complete ownership of your content and learning experience. Customize the interactive syllabi, emphasize the most important topics, and add your own material or notes in the eBook. The outcome-driven application helps you challenge every student, build their confidence, and empower them to be unstoppable.

LMS Integrated MindTap® Psychology

This access code will provide your with seamless access to their MindTap® Psychology resources from within your campus Learning Management System. Students will be prompted to enter this access code the first time that they click on a link in your course that includes Cengage content.

For the Student

Life-Span Development: A Case Book

ISBN-13: 9780534597672

Written by Barbara M. Newman (University of Rhode Island), Philip R. Newman (University of Rhode Island), Laura Landry-Meyer (Bowling Green State University), and Brenda J. Lohman (Iowa State University), *LIFE-SPAN DEVELOPMENT: A CASE BOOK* uses lively, contemporary case studies to illustrate development transitions and challenges in every stage of life. The authors have chosen these cases for their ability to fascinate, engage, and stimulate. Together with thought-provoking questions for analysis, the case studies create a learning experience that helps readers use multiple perspectives to analyze and interpret life events.

MindTap for Psychology

MindTap for *Development Through Life: A Psychosocial Approach* puts everything you need for class in one, easy-to-navigate place. MindTap includes an integrated eBook, assignments, practice quizzes, videos, and more, all designed to help you be a more successful student. MindTap for *Development Through Life: A Psychosocial Approach* can be purchased at www.cengagebrain.com.

About the Authors

Courtesy of Philip and Barbara Newman

Philip R. Newman (Ph.D., University of Michigan) is a social psychologist whose research has focused on the transition to high school as well as on group identity and alienation. His current project is a book about how high schools can better meet the psychosocial needs of adolescents. He has taught courses in introductory psychology, adolescence, social psychology, developmental psychology, counseling, and family, school, and community contexts for development. He served as the director for research and evaluation of the Young Scholars Program at the Ohio State University and as the director of the Human Behavior Curriculum Project for the American Psychological Association. He is a fellow of the American Psychological Association, the Society for the Psychological Study of Social Issues (SPSSI), and the American Orthopsychiatric Association. For fun, Phil enjoys photography, reading mysteries, attending concerts and Broadway plays, and watching baseball. He homeschooled his three children through elementary and middle school.

Barbara M. Newman (Ph.D., University of Michigan) is a professor emeritus in the department of Human Development and Family Studies at the University of Rhode Island. She has also been on the faculty at Russell Sage College and the Ohio State University, where she served as department chair in Human Development and Family Science and as associate provost for faculty recruitment and development. She has taught courses in life-span development, adolescence, human development and family theories, and the research process. Dr. Newman's current research focuses on the sense of belonging among college students, with particular attention to students in minoritized groups. She is a member of an inter-university research team investigating the developing sense of purpose among students with disabilities. For fun, Barbara enjoys reading mysteries, practicing the piano, making up projects with her grandchildren, taking walks along Narragansett Bay and Block Island Sound, and spending time with her family.

Together, the Newmans have worked on programs to bring low-income minority youth to college and have studied the processes involved in their academic success. They are co-authors of 13 books, including a recent book on theories of human development, and numerous articles in the field of human development. They met by the Mason Hall elevator at the University of Michigan, fell in love at first sight, and have been married for 50 years.

Human development is a social enterprise. Ideally, lives unfold in a network of caring relationships as people engage in productive action within stimulating, safe environments. The young ones observe and imitate their elders; the older ones care for and encourage the young. We strive to understand the ways that individuals make meaning and shape the direction of their lives from the creative, playful work of childhood to the inspiring wisdoms of elderhood.

LEARNING OBJECTIVES

1. Explain the basic assumptions that guide the orientation of the text.
2. Describe the psychosocial approach to the study of development, including the interrelationship among the biological, psychological, and societal systems.
3. Compare historical changes in life expectancy. Analyze individual and group factors that contribute to longevity.

Chapter Summary

— **CASE STUDY** Ruth Hamilton —

Ruth Hamilton was born in 1898 and died in 2008. Over her long life, she was a teacher, wife, mother, businesswoman, radio talk-show host, legislator, and world traveler. Ruth's advice: "No matter what your age, keep learning. Put this motto on your mirror so that you'll see it: Every day without learning something is a day lost" (Enkelis, 2000, p. 95).

Ruth grew up in the farming town of Alta, Iowa, where she graduated from high school and went on to Iowa State Teacher's College. "At that time, they needed teachers so badly in the country schools that they had crash courses," Ruth recalls. "We could get the two years of training that was needed for a teaching certificate in twelve weeks, but we had to go to school night and day to do it" (Enkelis, 2000, pp. 91–92). She began teaching in a one-room country schoolhouse with children in first, second, fourth, and eighth grades. "All the kids could hear all of the recitations. It was fascinating. I think all the kids benefited," Ruth noted (Enkelis, p. 92).

In July 1920, Ruth met Carter Hamilton while she was watching a sandlot baseball game during a 4th of July celebration. She and Carter fell in love. Carter had been drafted by the Cleveland Indians, and when he came to say goodbye, he said he'd like her to come with him, but he knew her parents wouldn't agree unless they were married, so he thought getting married would be a good idea. Ruth took a half day off from teaching, and they went to Des Moines and were married 8 months after they met. Since married women couldn't teach (a widespread practice in the United States at the turn of the 20th century), she tried to keep it a secret. But her students found out and told other teachers. She had to go before the school board, and they agreed to change the rules.

Carter played baseball in the summers and went to college and later to medical school in the off-season. Once Carter completed his internship they settled in Iowa for a while. Carter wanted Ruth to give up teaching and stay at home, but Ruth could never accept this role. She was an energetic, curious, and active person. Even after they adopted their son Peter, she continued to pursue her own interests.

While in Iowa, Ruth continued teaching. Then Carter's specialization as a radiologist took them to Philadelphia. When they moved to Philadelphia, Ruth expanded her professional life by teaching over the radio. In the 1930s, Ruth was one of America's first female radio talk-show hosts. On a whim, Ruth got a loan and bought a building where she set up a women's dress shop. She operated the shop successfully for two years and then sold the building for $2,000 profit. With that money, she bought a log cabin and 10 acres of land in New Hampshire, where she and her husband vacationed.

In 1937, Ruth began what was to become a life-long interest in travel. She took a 2 month trip to Europe to explore her family history, including travel to Denmark and Sweden. At this time, she went to Berlin where she remembers seeing Adolph Hitler and having a glimpse of his magnetism and the way women swooned when they saw him. She became well aware of how dangerous he was and tried to talk to people back home about this.

Following Carter's death in 1948, Ruth moved into the cabin in New Hampshire. From the ages of 50 to 90, Ruth developed a life of international travel and political leadership. She traveled extensively beginning in the 1950s through 1990, giving lectures and writing articles about the countries she visited. She became involved in politics, including the political campaigns of Eugene McCarthy, George McGovern, and Jimmy Carter. She was the first woman elected to the New Hampshire legislature, where she was elected twice from 1964 to 1973. She took an active role in legislative issues, including reducing the legal voting age, issues related to wiretapping and eavesdropping, and legislation to have inspections and licensing for residential homes that care for senior citizens. In 1986, she was honored as an "Unsung Heroine" by the Claremont New Hampshire Commission on the Status of Women.

In her 90s Ruth moved to an assisted living community in Florida where she became a member of "Growing Bolder," a social networking site for older adults. At age 109, she was recognized on that site as the world's oldest video blogger. You can watch her blog about the power of curiosity at https://www.growingbolder.com/ruth1898-on-the-power-of-curiosity-1499/.

Ruth was an amazingly active, enthusiastic, outgoing person. She once said, "I just wish I could live to be one thousand years old because there are so many things that I want to see improved" (Enkelis, p. 95).

Imagine for a moment living for more than 100 years into an unknowable future. Think of Ruth Hamilton, starting out as a teacher in a one-room country school and eventually sharing her thoughts over the Internet as a video blogger. Finding love in a most unexpected way, adopting a son, hosting a radio talk show, traveling the world, building a new political career after the early death of her husband, advocating for the young and the old—these are all segments of a life built on intelligence, resilience, and optimism. Ruth's sense of agency—her ability to set goals and make things happen to achieve these goals—her curiosity, and her love of learning propelled her through challenges, losses, and accomplishments from one chapter of her life to the next.

If you are intrigued by the life of Ruth Hamilton, if you wonder how and why people make the choices that they make, how they cope with adversity, and how they maintain a sense of purpose, you have come to the right place—the study of human development. You are about to explore theory and research that have accumulated over the years about how individuals make sense of their experiences, make decisions and take actions to adapt to their environments, cope with challenges, and continue to develop from one period of life to the next. This process is as individual as each person's life story. It is influenced by the quality of one's social relationships, as well as such factors as gender, ethnicity, cultural identity, health, socioeconomic status, education, sexual orientation, physical abilities and disabilities, and historical and social contexts. Even though each person's life is unique, common patterns of experience and meaning allow us to

Blend Images - Ariel Skelley/Getty Images

Growth occurs at every stage of life. Within a large family, we have opportunities to observe family resemblances and individual differences, patterns of continuity from year to year, as well as evidence of maturation and change.

know and care for one another and contribute to one another's well-being. As you study the life-span approach to human development, you will learn to identify and evaluate patterns of transition and transformation from one period of life to another. In this process, you will come to recognize that there are both intergroup differences and individual variations within groups.

Several features of the chapters are intended to foster your critical thinking and to broaden your ability to link the theories and research presented in the text to important social issues. Boxes labeled "Applying Theory and Research to Life" and "Human Development and Diversity" end with a set of critical thinking questions. Case studies are followed by prompts entitled "Using What You Know." And interspersed in the text are encouragements for "Further Reflection." All these features are designed to engage you as an active reader and to help you link what you are reading about to your own personal life experiences.

This chapter provides a brief introduction to three topics that are central to the study of the **life span**. First, we outline six **assumptions** about human development that guide the orientation of the text. Second, we introduce the concept of a **psychosocial approach** to development. Third, we review data about **life expectancy** to start you thinking in a concrete way about the course of your life and the decisions you make that may directly influence your life story. ●

Assumptions of the Text

OBJECTIVE 1 Explain the basic assumptions that guide the orientation of the text.

Our perspective on development through life makes the following six assumptions that are critical to the orientation of this book:

1. *Growth occurs at every period of life, from conception through elderhood.* At each period, new capacities emerge, new roles are undertaken, new challenges must be faced, and, as a result, a new orientation toward self and society unfolds. The concept of life-span development implies **plasticity**, a capacity for adaptive reorganization at the neurological, psychological, and behavioral levels.
2. *Individual lives show both continuity and developmental change over time.* An awareness of the processes that contribute to both continuity and change is central to an understanding of human development. **Continuity** refers to stability in characteristics from one period of life to another. It also refers to a sense of sameness over time built on a history of memories, identity, and reflected self. **Developmental change** refers to patterns of growth and reorganization. Change may be attributed to biological maturation, systematic socialization, self-directed striving, and the interaction of these forces.
3. *We need to understand the whole person, because we function in an integrated manner.* To achieve such an understanding, we need to study the major developments in physical, social, emotional, and cognitive capacities and their interrelationships. For example, what people think about moving to a new town is influenced by their social roles, their expectations and goals, their feelings in the situation, and their physical health or limitations. Each system serves as a stimulus for the others, requiring an integration of all these capacities in order to produce an adaptive response.
4. *Behavior must be interpreted in the context of relevant settings and personal relationships.* Human beings are highly skilled in adapting to their environments. The meaning of a given behavior pattern or behavior change must be interpreted in light of the significant physical and social environments in which it occurs. While individuals are changing, so are their environments. As children grow older, they may have new siblings; their parents will age; and they may encounter new technologies, health care interventions, or educational approaches that alter the nature of daily life. As a result, we need to be able to consider how changes in the nature of the person are impacted by changes in the environments in which they function.
5. *People contribute actively to their development.* These contributions take many forms, including the expression of tastes and preferences, choices and goals, and one's willingness to embrace or resist cultural and societal expectations. One of the most critical ways in which a person contributes to his or her development is through the creation of significant social relationships, which then form a context for social support and socialization. Some societies offer more opportunities for choice and promote a person's ability to mold the direction of development, whereas others have fewer resources, are more restrictive, or place less value on individuality (Veenhoven, 2000).
6. *Diversity is a product of the interaction of the biological, the psychological, and the societal systems.* Diversity refers to the differences that exist among people. Diversity is built into the architecture of the human genome.

It increases as individuals encounter new settings and make unique meaning of their experiences. Social identities, economic resources, and educational opportunities are all aspects of the societal system that contribute to diversity. The differences that exist among people are part of what protects the human species and allows it to adapt across a wide and changing range of environments. Throughout the chapters, we highlight the nature of individual, group, and cultural differences and feature some specific examples in the **Human Development and Diversity** boxes.

FURTHER REFLECTION: *Describe three examples of assumption 5, illustrating how people's decisions and goals influence the course of their development.*

A Psychosocial Approach: The Interaction of the Biological, Psychological, and Societal Systems

OBJECTIVE 2 Describe the psychosocial approach to the study of development, including the interrelationship among the biological, psychological, and societal systems.

Erik Erikson (1963, p. 37) wrote that human life as the individual experiences it is produced by the interaction and modification of three major systems: the biological system, the psychological system, and the societal system. Each system can be examined for patterns of continuity and change over the life course. Each system can be modified by self-guided choices. The integration of the biological, psychological, and societal systems leads to a complex, **biopsychosocial** dynamic portrait of human thought and behavior.

In many developmental analyses of behavior, you may come across the terms "nature" and "nurture." These terms are often used as shorthand for thinking about the roles of genetics and environments in guiding development. Typically, nature refers to genetic predispositions or potentials and inborn or innate qualities that guide the unfolding of capacities and traits. Nurture refers to the patterns of socialization and care that the person receives. The science of development has often been presented as the study of the ways nature and nurture interact to produce a certain outcome, for example intelligence, assertiveness, or hopefulness.

In *Development Through Life* we take a somewhat different approach by expanding the analysis to three interrelated systems: the biological, the societal, and the psychological systems. Rather than thinking of the developing person as passively shaped by forces of nature and nurture, we think of the person as actively engaged in the developmental process through the application of the psychological system. The psychological system is the **meaning-making** system that seeks out information, integrates information from many sources, and evaluates experiences as positive or negative, encouraging or threatening. Depending on their experiences and predispositions, some people are more likely to take the initiative in shaping the course of their development while others are more passive. The psychosocial approach is an attempt to sketch the ways that a person's worldview and sense of self in society change as a product of the interaction of these three dynamic systems over the course of life.

The Biological System

The **biological system** includes all those processes necessary for the physical functioning of the organism and for mental activity (see FIGURE 1.1 ▶). The brain and spinal cord (the central nervous system) and the peripheral nervous system are components of the biological system through which all sensory information is received, processed, and transmitted to guide behavior. Biological processes develop and change as a consequence of genetically guided maturation; environmental stimulation and resources, including social interactions, cognitive challenges, and nutrition; exposure to environmental toxins; encounters with accidents and diseases; and lifestyle patterns of behavior.

We can imagine that when Ruth Hamilton fell in love with Carter, this resulted in many changes to her biological system including changes in hormones, sexual behavior, eating and sleeping patterns, and physical activity. Falling in love is a major change factor that brings out a cascade of modifications to the biological system. As a result of some feature of the biological system which is not disclosed in the case, Ruth and Carter were not able to have children. This biological problem posed new challenges to Ruth's self-concept and led to the eventual decision to adopt a son, thereby altering her social role.

Some components of the biological system influence the maturation of other components of the biological system. For example, when the infant's limbs achieve a certain length and

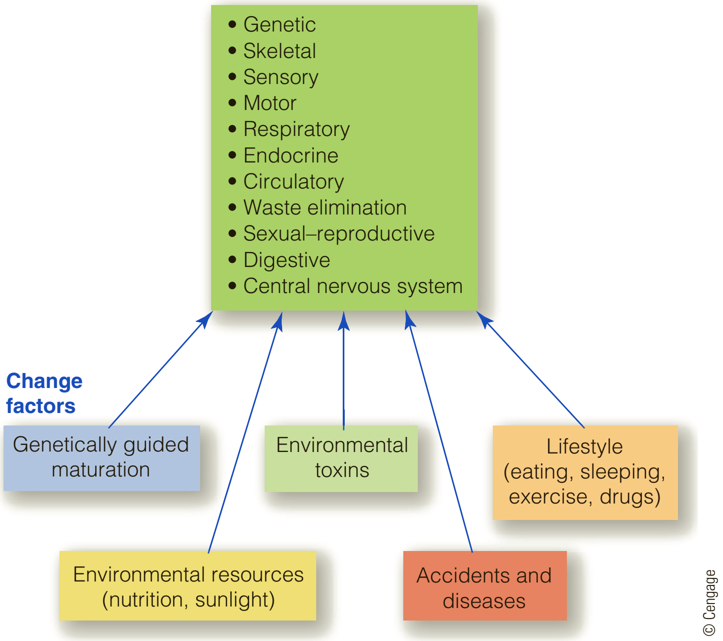

FIGURE 1.1 ▶ THE BIOLOGICAL SYSTEM

muscle strength, the baby is able to reach out from a sitting position to begin crawling—a new form of locomotion. This results in new opportunities for exploration of the environment which in turn results in new neural networks and changes in the organization of the brain. The biological system is itself a multilevel, dynamic system in which maturation at one level can have profound, and sometimes unexpected, consequences for maturation at another level.

Cultures differ in their support of physical growth and health, depending on the availability of adequate nutritional resources, approaches to the treatment of illness, exposure to environmental toxins and hazardous conditions, and the availability of information about healthy lifestyle choices.

In the case of Ruth Hamilton, two examples of the influences of the biological system on her life experiences are her **longevity** and her good **health**. Looking at Figure 1.1, try to formulate a list of other aspects of the biological system that may have been important in shaping Ruth Hamilton's life story. The theme of health is synergistically integrated throughout the text. At each stage of life, health care practices, access to health care resources and knowledge, and individual differences in health-related risks and resilience have an impact on a person's developmental trajectory.

The Psychological System

The **psychological system** includes those mental processes central to a person's ability to make meaning of experiences and take action (see FIGURE 1.2 ▶). Emotion, memory, perception, motivation, thinking and reasoning, language, symbolic abilities, and one's orientation to the future are examples of psychological processes. When these processes are integrated, they provide the resources for processing information, solving problems, and navigating reality. In the case of Ruth Hamilton, we can appreciate the influence of the psychological system in her motivation, persistence, independence, ingenuity, personal goals, and feelings of self-determination.

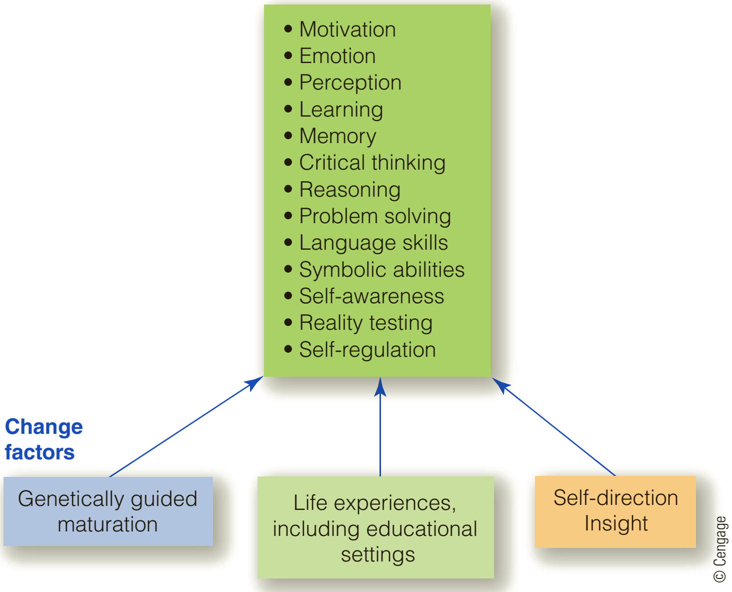

FIGURE 1.2 ▶ THE PSYCHOLOGICAL SYSTEM

Like the biological processes, psychological processes develop and change over one's life span. Psychological change is guided in part by genetic information. The capacity for intellectual functioning and the direction of cognitive maturation are genetically guided. Some genetic diseases result in intellectual impairment and a reduced capacity for learning. Psychological change also results from the accumulation of experiences and from encounters with various educational settings that impact brain development and result in new cognitive structures and new approaches to problem solving. Psychological processes can be enhanced by numerous life experiences including the quality of parenting one receives; interactions with friends; opportunities for play of all types; travel; reading; exposure to music, art, poetry, and the dramatic arts; and schooling.

Finally, psychological change can be self-directed. A person can decide to pursue a new interest, learn another language, or adopt a new set of ideas. Ruth Hamilton took time for self-discovery through travel, which expanded her worldview. By retreating to New Hampshire after the death of her husband, she gave herself time for reflection and recovery in a place that she and Carter enjoyed together. People can strive to achieve new levels of **self-insight**, to be more aware of their thoughts and feelings, and to be less defensive. Meditation and mindfulness practice are examples of techniques people are using to achieve these goals. There is evidence to suggest that self-insight is a vital component of positive mental health (Wilson, 2009). What strategies do you use to alter your worldview or achieve new levels of self-insight?

Meaning Making

The meaning we make of our experiences changes over the course of life. Think about the concept of love as an example. In infancy, love is almost entirely physical. It is the pervasive sense of comfort and security that we feel in the presence of our caregivers. By adolescence, the idea of love includes loyalty, emotional closeness, and sexuality. In adulthood, the concept of love may expand to include a new emphasis on companionship and open communication. The need to be loved and to give love remains important throughout life, but the self we bring to a loving relationship, the context within which the relationship is established, and the signs we look for as evidence of love change with age.

Meaning is created out of efforts to interpret and integrate the experiences of the biological, psychological, and societal systems. A primary focus of this meaning making is the search for **identity**. Humans struggle to define themselves—to achieve a sense of identity—through a sense of connectedness with certain other people and groups and through feelings of distinctiveness from others. We establish categories that define to whom we are connected, about whom we care, and which of our own qualities we admire. We also establish categories that define those to whom we are not connected, those about whom we do not care, and those qualities of our own that we reject or deny. These categories provide us with an orientation toward certain kinds of people and away from others, toward certain life choices and away from others. The psychosocial perspective brings to light the dynamic

altrendo images/Juice Images/Getty Images

The desire to experience a loving relationship remains strong throughout life. However, the self one brings to a loving relationship changes at each stage. How might experiences of love change from adolescence to early adulthood to later adulthood?

interplay of the roles of the self and the others, the I and the We, as they contribute to the emergence of identity over the life course.

The Societal System

The **societal system** includes social roles; social support; **culture**, including rituals, myths, and social expectations; media; leadership styles; communication patterns; family organization; ethnic and subcultural influences; political ideologies and forms of government; religions; patterns of economic prosperity or **poverty**; conditions of war or peace; and exposure to racism, sexism, and other forms of discrimination, intolerance, or intergroup hostility. The societal system encompasses those processes that foster or disrupt a person's sense of social integration and social identity (see FIGURE 1.3 ▶). Through laws and public policies, political and economic structures, and educational opportunities, societies influence the psychosocial development of individuals and alter the life course for future generations (de St. Aubin, McAdams, & Kim, 2004). Societal processes may change over one's life span. The process of modernization may bring exposure to new levels of education, new technologies, encounters with more diverse groups of people, and new forms of work. These changes are likely to result in more individualistic values, new priorities about which skills are valued, and changing patterns of family life (Greenfield, 2009).

FIGURE 1.3 ▶ THE SOCIETAL SYSTEM

Technological innovations can modify the societal system. For example, television, cell phones, personal computers, and the Internet are technological innovations that have modified people's access to information and relationships. These technologies have altered children's roles, providing them with resources that can allow them to function at new levels of autonomy and competence. In many families, children teach their parents and grandparents how to make use of new technologies, thus expanding their role. Cell phones reduce barriers to communication, a change that has multiple impacts on patterns of communication—some positive and some negative.

Historical events can also influence the societal system, altering social roles, access to resources, economic conditions, and one's sense of personal safety or security. Events such as the destruction of the World Trade Towers in 2001, the economic collapse of 2008, the devastation of Hurricane Katrina and Hurricane Sandy, the bombing at the Boston Marathon, and the shooting at the Sandy Hook Elementary School have an enduring influence on people's sense of safety, economic security, and confidence in key social institutions. Positive events, such as the Supreme Court rulings regarding marriage equality and the passage of the Affordable Health Care Act have provided social validation and access to resources that contribute to a more secure, predictable life.

In this text, the role of culture is emphasized as it contributes to the pattern, pace, and direction of development. Societies differ in their **worldviews**, including the emphasis placed on collectivism or individualism, ideas about the major sources of stress and ways to alleviate stress, and beliefs about which groups are viewed as more powerful or more important than others. Societies differ in their emphasis on and belief in science, spirituality, and fatalism. They differ in their **age-graded expectations**, such as when a person is considered to be a child, an adult, or an elder, and how people in these age roles should be treated. They differ in their definitions of morality, beauty, bravery, wealth, and other ideals that may define individual and group aspirations. As you read the text, you will encounter **Human Development and Diversity** boxes. These boxes provide examples of how norms of development might be viewed differently in different cultures or ethnic groups. We hope these examples will help sensitize you to the role of culture in defining what may be viewed as appropriate, optimal, or normal behavior.

The societal system is illustrated in several ways in the case of Ruth Hamilton. Women did not have the right to vote in the United States until 1920. By then, Ruth was 22. Early in her life, there was a teacher shortage. The societal system responded by providing training opportunities, and Ruth took advantage of this program. When she married Carter, the policies of the school prohibited married women from teaching. In the early part of the 20th century it was considered improper for married women to work. Although many women were trained as teachers, they were forced to leave their profession once they were married (Enkelis, 2000). Ruth, however, pushed back against these restrictions, hoping to continue in her work. Due to her good performance and the need for teachers in her town, the societal system changed in order to keep her in the school. This specific example illustrates that the societal system can impose constraints, but that there are many ways that individuals and groups can alter the societal system.

The Psychosocial Impact of Poverty

In thinking about the impact of societal factors on development, we want to highlight the context of poverty as a major obstacle to optimal development. (See the **Applying Theory and Research to Life** box Poverty.) Racism, sexism, ageism, homophobia, and discrimination against individuals with physical, intellectual, and emotional disabilities are other examples. However, under conditions of poverty, individuals have fewer options and less opportunity to escape or avoid these other societal deterrents. Poverty has powerful and potentially pervasive effects on the biological and psychological systems across the life span.

The government, as an arm of the societal system, defines poverty in order to determine who is eligible for certain resources and services. The **poverty threshold** is defined as the minimum cash income needed to support a person or a family in meeting basic needs of daily living. The poverty threshold varies by family size, number of children, and the age of the householder (Bishaw, 2012). Certain terms are used in the literature to refer to the level or intensity of poverty: Extreme poverty—income less than 50 percent of the poverty threshold; Poverty—income less than 100 percent of the poverty threshold; and Low income—income less than 200 percent of the poverty threshold.

The original definition of the poverty threshold was created in the 1960s. It was formulated based on the idea that under subsistence conditions, a family would need to spend about one third of its income on basic food needs; so the poverty threshold was set at three times the cost of a basic food budget. Each year, the dollar value of this minimum level is recalculated based on the cost of living index. Critics argue that this approach to defining poverty is inadequate in today's economy. The cost of food has remained relatively low in comparison to the cost of housing, transportation, health care, energy, and child care (for families with young children). They suggest that the poverty threshold should be more like five times the cost of a basic food budget. Furthermore, the cost of living and employment opportunities vary by states and regions of the country, but the basic poverty threshold is set at a national level and is applied without consideration for these regional variations (Grusky, Mattingly, & Varner, 2015). Based on the definition used by the U.S. Census Bureau, in 2014 there were 46.7 million people in poverty (U.S. Census Bureau, 2015).

In and of itself, poverty does not place inevitable limits on development. There are many instances of children who grew up in poverty and achieved eminence (Harrington & Boardman, 2000). Many children flourish under conditions of meager family resources. However, it is well documented that poverty increases the risks that individuals face, including risks associated with malnutrition, poor quality health care, living in poor quality and overcrowded housing, living in a hazardous or dangerous neighborhood, and attending ineffective schools. Poverty is linked with reduced access to basic resources associated with health and survival (Crosnoe & Huston, 2007; Yoo, Slack, & Holl, 2009). Exposure to these risk factors early and continuously throughout childhood is associated with higher incidences of health problems, greater challenges in achieving the developmental tasks of each life stage, disruptions in family and work trajectories, and reduced life expectancy (Hayward, Crimmins, Miles, & Yang, 2000; Knitzer, 2007).

APPLYING THEORY AND RESEARCH TO LIFE

Poverty

Conditions Leading to Poverty

A number of societal factors contribute to the percentage of families living in poverty: (1) the decline in well-paying manufacturing and management jobs due to downsizing and outsourcing; (2) large numbers of single-mother households; (3) the erosion of the economic safety net for poor families, including the decline in cash transfers and benefits to families in the Transitional Assistance to Needy Families (TANF) program; (4) natural disasters such as hurricanes and floods; and (5) the decline in the purchasing power of the minimum wage. The actual buying power of the minimum wage has declined by over 30 percent since the 1960s (Siegmund, 2015).

Poverty is transitory for some families—such as when a wage earner becomes unemployed and then finds new work—but persistent over the life course for others. For unmarried women who become mothers in adolescence, poverty is often a result of interrupted education, the inability to work full time (usually because of time needed to care for their children), and the low-paying jobs that are available to those with limited educational attainment. Furthermore, many of these young mothers are growing up in families that are already living in poverty. Eighty-six percent of children whose parents do not have a high-school diploma live in low-income families (Jiang, Ekono, & Skinner, 2015).

Divorce places many women and their children into poverty. In many instances, the family was already encountering financial strain, one of the primary factors associated with divorce. However, following divorce, it is not uncommon for women to experience a substantial drop in family income (Gadalla, 2009). The poverty rate of custodial mothers in 2011 (32 percent) was significantly higher than the poverty rate for custodial fathers (16 percent). The level of poverty experienced by newly divorced women is aggravated by the failure of many fathers to pay child support (Putze, 2014). Poverty after divorce may be transitory if women remarry and their family income returns to pre-divorce levels (Reilly, 2009). With increases in women's education and career prospects, and laws enforcing the payment of child support, women may be more likely to emerge from poverty after divorce in the future than was the case in the past.

Negative Consequences of Poverty

Persistent poverty and exposure to poverty during infancy and early childhood are associated with greater vulnerability and more negative consequences to physical health, cognitive development and school achievement, and mental health. Specific family characteristics increase the likelihood that children in poor and low-income families will experience negative academic and health outcomes. These include:

Households without English speakers
Large families
Low parental education
Residential mobility
Single-parent families
Teen mothers
Unemployed parents

Children with three or more of these risk factors are the most vulnerable to early and continuing negative outcomes (Robbins, Stagman, & Smith, 2012).

Physical Health. Exposure to poverty during the prenatal period is associated with increased risks for having premature babies and babies that are small for gestational age (Nepomnyaschy, 2009). Children in low-income families are more likely to be in fair or poor health and lack access to quality health care. Children in low-income families often lack treatment for existing physical health problems, such as asthma, or go untreated for infections that then become more serious and can result in long-term chronic conditions. For a family in poverty, a visit to a doctor that costs $75 is a significant and possibly prohibitive expense.

A person's health is not only related to their current level of income, but also to their exposure to economic hardship from childhood through adulthood. Conditions of poverty create a heightened level of wear and tear on the body, brought about by the need to continuously respond to stress. Over time, the cumulative impact of these conditions results in accelerated physical deterioration leading to increased rates of diseases and an earlier age of death (Fuller-Rowell, Evans, & Ong, 2012; Williams, 2012).

Academic Achievement. Higher family income is consistently associated with higher academic achievement. Children in low-income families begin kindergarten with a substantial disadvantage with regard to specific academic skills such as counting, recognizing letters of the alphabet, and reading. By the time they are in the third grade, children in low-income families have an average vocabulary of 4,000 words compared to a vocabulary of 12,000 words for children from middle-income families (Klein & Knitzer, 2007).

Research on seasonal fluctuations in learning shows that children from low-income families and low-resource communities have substantially fewer opportunities over the summer than their middle-income peers. Year after year, they begin school behind their middle-income peers. In addition, inequities in school resources and educational opportunities across communities are well documented. As a result, by the time children from low-income families reach the ninth grade, they have significantly lower test scores, are less likely to be placed in college-preparatory tracks, and are more likely to drop out of high school than their higher socioeconomic (SES) peers (Alexander, Entwisle, & Olson, 2007).

In schools with students from a diversity of economic backgrounds, the students from low-income families tend to be viewed as less competent by the teachers and their wealthier classmates. This may create an added burden on their academic self-concept and result in lower academic performance (Crosnoe, 2009). Fewer adolescents who live in low-income families apply to and attend college than their middle and higher income peers. A national longitudinal study followed students from 2002 when they were in tenth grade, through 2012, when they were age 24. Students could be linked to their families' socioeconomic (SES) group based on their parents' income, education, and occupation. Fourteen percent of the low SES group had a bachelor's degree or higher compared to 29 percent of the middle SES group, and 60 percent of the high SES group (U.S. Department of Education, 2015).

Nathan Benn/Getty Images

Poverty is a powerful characteristic of the societal system. Children growing up in poverty are exposed to stressors and hazards that can severely restrict development.

Mental Health. Early experiences shape the establishment of neural networks, including the way the brain processes information and manages emotions. A key ingredient of early brain development is the quality of caregiving relationships, especially the ability of caregivers to be appropriately nurturing, responsive, and stimulating. Children from low-income families are more likely to be exposed prenatally to factors such as maternal malnutrition, cigarette smoke, alcohol, and environmental toxins that disrupt neural development. Infants and young children in impoverished families are more likely to be exposed to parental depression, other diagnosable mental disorders, and parental adversities including domestic violence, substance abuse, and residential instability or homelessness that disrupt or destabilize caregiving. In addition, threats to safety are of special concern to children living in low-income neighborhoods where exposure to uncontrollable violence on the streets and near the school is associated with symptoms of post-traumatic stress (Caughy, Nettles, O'Campo, & Lohrfink, 2006).

A combination of parental mental health problems, neighborhood instability, and chaotic school environments all contribute to the emergence of short- and long-term mental health consequences including depression, acting-out behaviors, difficulty concentrating, and school problems. Living in poverty is associated with higher rates of learning problems and diagnosable disorders in older children (Knitzer & Cooper, 2006). These often lead to juvenile justice involvement and higher school dropout rates.

Critical Thinking Questions

1. Explain what is meant by the phrase "the cycle of poverty."
2. Create a table that shows how the experiences of growing up in poverty might influence a person's physical health, academic achievement, and mental health as an adolescent and as an adult.
3. Propose some immediate steps that a society could take to reduce the negative consequences of poverty.

With 45 percent of children growing up in low-income families, the United States faces a serious long-term challenge (DeNavas, Walt, & Proctor, 2015; Jiang, Ekono, & Skinner, 2015). Evidence suggests that children growing up in poverty are likely to experience multiple physical and mental health problems, which often grow worse as they encounter the stressors of poverty in adolescence and adulthood. Problems in cognitive and behavioral functioning have implications for academic achievement, job acquisition and performance, and the formation of long-term, stable relationships. The challenge for the field of human development is to inform policies and programs that will buffer children and families from the negative consequences of poverty (Yoshikawa, Aber, & Beardslee, 2012).

Because of the complex and pervasive impact of poverty on development, we introduce it as a fundamental societal theme. Issues related to the impact of poverty on patterns of individual development and family life will be addressed in more detail in subsequent chapters.

Overview of the Psychosocial Approach

The psychosocial approach seeks to understand development as a product of interactions among biological, psychological, and societal processes. Changes in one of the three systems (biological, psychological, or societal) generally bring about changes in the others. As an example, the psychological capacities for thinking about oneself and others develop over time as the social information-processing areas of the brain are stimulated (Adolphs, 2009; Grossman, 2013). The biological system recognizes and processes social stimulation. The societal system creates the contexts for social interactions and introduces complex patterns of values and priorities for social behavior. Further, the psychological system internalizes these values and assigns unique meaning to social events. So, for example, researchers find that in a task that requires recognition of one's own face and the face of a familiar other, Westerners, who tend to emphasize self-related events, recognize their own face more quickly, and East Asians, who tend to emphasize social connections among people, recognize the familiar other more quickly (Sui, Liu, & Han, 2009).

Throughout life, personal relationships occupy our attention. Some of these relationships are more important than others, but their quality and diversity provide a basis for the study of one's psychosocial development. As we progress through the stages of life, most of us develop an increasing capacity to initiate new relationships and to innovate in our thoughts and actions so as to direct the course of our lives.

At each period of life, people strive to master a unique group of psychological tasks that provides essential learning for social adaptation within their society. Each life stage brings a normative crisis, which is viewed as a tension between one's competencies and the new demands of society. People try to reduce this tension by using a variety of familiar coping strategies and by learning new ones. A positive resolution of each crisis yields new social abilities and a new understanding of the self and others that enhance a person's capacity to adapt successfully in succeeding stages. A negative resolution of each crisis typically results in defensiveness, rigidity, or withdrawal, which decreases a person's ability for successful social adaptation in succeeding stages.

— CASE STUDY Rose —

The case of Rose provides an opportunity to apply the concepts that were presented about the biological, the psychological, and the societal systems and their interactions to a real-life example.

Rose is a 60-year-old woman who has been having serious attacks of dizziness and shortness of breath as Thanksgiving approaches. Rose is usually active and energetic. In the past, she looked forward to entertaining her family, which used to include three married daughters, one married son, their spouses, and their children. However, her son has recently been divorced. Feelings between him and his ex-wife are bitter. Any attempts on Rose's part to communicate with her former daughter-in-law or granddaughter are met with outbursts of hostility from her son. Although Rose is very fond of her daughter-in-law and granddaughter, she knows that she cannot invite them to the family gathering without stirring up intense conflict with her son. Rose's daughters suggest having the dinner at one of their homes in order to prevent further conflict. They hope this solution will take some of the pressure off their mother and ease the attacks. Rose agrees, but her attacks continue.

Case Discussion

How are the biological, psychological, and societal systems involved in Rose's situation? We might hypothesize that her physical symptoms—dizziness and shortness of breath—are due to an inability to resolve a difficult family conflict. Psychological and societal demands may elicit responses from the biological system, as they commonly do in people under stress. The biological system often alerts a person to the severity of a threat or crisis through the development of physical symptoms. Rose might visit her family doctor in order to evaluate whether her symptoms are a result of high blood pressure or early signs of heart disease. There may be medication that can help reduce these symptoms, allowing Rose to feel less anxious and more confident about her role in the family.

Rose's psychological system is involved in interpreting her son's behavior, which she views as forcing her to choose between him and her daughter-in-law and granddaughter. She might also use psychological processes to try to arrive at a solution to the conflict. So far, Rose has not identified any satisfactory solution. Although she can avoid the conflict most of the time, the impending Thanksgiving dinner is forcing her to confront it directly.

The psychological system includes Rose's self-concept as well as her emotional state. Through memory, Rose retains a sense of her family at earlier periods, when they enjoyed greater closeness. Having to face a Thanksgiving dinner at which she will feel angry at her son or guilty about excluding her daughter-in-law and granddaughter places her in a fundamental conflict. The Thanksgiving meal is also a symbolic event, representing Rose's idea of family unity, which she cannot achieve. Rose will lose the sense of family unity that she has tried to preserve.

The societal system influences the situation at several levels. First, there are the societal expectations regarding the mother role: Mother is nurturing, loving, and protecting. But Rose cannot be nurturing without sending messages of rejection either to her son or to her daughter-in-law and granddaughter. Second, social norms for relating to various family members after a divorce are unclear. How should Rose behave toward her son's former spouse? How should she relate to her grandchild if her son is no longer the child's custodial parent? Rose is confused about what to do. Third, the Thanksgiving celebration has social, religious, and cultural significance. This family ritual was performed in Rose's home when she was a child, and she has carried it through in her own home as an adult. Now, however, she is being forced to pass the responsibility for this gathering to her daughter before she is ready to do so and, as a result, Rose is likely to feel a special sense of loss.

CASE ANALYSIS Using What You Know

1. How does this case illustrate the interconnections among the biological, psychological, and societal systems?
2. Given what you know about the assumptions of psychosocial theory, how might Rose's stage of development influence her perceptions of this situation and her approach to coping with this conflict?
3. How might you pose a research question based on the information raised in this case study? (For example, how likely is it that parents experience health problems following their child's divorce?)

4. How might Rose's social support system, especially her daughters, be involved in helping her cope with this conflict?
5. How might the current conflict impact future psychosocial development for Rose? Consider the assumptions of the text as you try to answer this question.

FURTHER REFLECTION *From your own experiences, what are two examples of how the biological, the psychological, and the societal systems interact?*

How does your culture view the stages of life? For example, what messages from your family, community, or ethnic group influence your understanding of the distinctions between childhood, adolescence, adulthood, and elderhood?

How do these cultural beliefs influence the way you make meaning of your current stage of life?

The Life Span

OBJECTIVE 3 Compare historical changes in life expectancy. Analyze individual and group factors that contribute to longevity.

Many of our most important life decisions are made with either an implicit or explicit assumption about how long we expect to live. These assumptions have an impact on our behavior, self-concept, attitudes, and outlook on the future. For example, Colleen expects to live to be about 80 years old. She reasons that there is no rush about getting married because, even if she waits until she is 40, she will still have 40 years of married life, and that is a long time to get along with one partner. In contrast, Tyler expects to live to be about 25. Several of his older brothers' friends died of gunshot wounds, others died from drug overdoses, and some died in prison. He believes that he may as well take all the risks and have all the fun he can in life, because his time is short. He hopes to have lots of babies by many women so that some part of him will live on. Marie is celebrating her 90th birthday. She had expected to live to about age 75. Most of her friends and all her older siblings are dead. She is puzzled by the idea of having lived so long and sometimes wonders about the purpose of her long life.

People's expectations about how long they will live influence their life planning and what they think they need to accomplish in order to provide some security in adulthood and old age. There are national trends, but there are also regional, racial/ethnic, gender, and economic differences in longevity that can influence people's expectations about length of life, life planning, and the timing of transitions into adulthood.

Life Expectancy

Life expectancy is a statistical projection of the number of years one can expect to live. The task of mapping one's future depends on how long one expects to live. Naturally, for specific individuals, we can make only rough predictions. We know that some lives may be cut short by a disaster, an accident, or an illness. On the other hand, some people, like Ruth Hamilton, are exceptionally long lived.

As the life expectancy has changed, a complex network of policies and practices are coming into question. These include the idea of retirement, the age of retirement, the nature of adult retirement communities, dating and remarriage in later life, second or third careers, and educational opportunities for elders.

In the 1930s, the U.S. government set 65 as the age of retirement in the Social Security system. The selection of this age was a combination of a pragmatic decision based on the typical age for retirement in a few private and state-based systems as well as actuarial data. In the late 1930s and 1940s, slightly over 50 percent of men survived from age 21 to age 65, and those who survived to age 65 had about another 13 years to live. In 2010, those who reached age 65 could expect an average of another 19 years of life. People have to think about how to support themselves for 20 or 30 years, leading to new ideas about retirement and financial independence in later life.

As people come to expect that life will last into the 80s and 90s, their ideas about the ideal age for assuming adult roles change. A longer life expectancy seems to be related to a more gradual transition into adulthood, including a later age at marriage, older age for having children, and more occupational transitions. A healthier later life changes ideas about the nature of retirement or even the whole concept of retirement. Many older adults in their 70s do not feel "too old" to work. There is some evidence to suggest that working actually helps sustain cognitive well-being in later life.

Life expectancy is also a useful "bellwether" of societal modernization and progress. Improvements in education, nutrition, water quality, infant and maternal health, and access to medical care are all associated with gains in longevity. We use average length of life as one indication that a country is doing well or doing poorly in meeting basic human needs.

Table 1.1 presents data on the average life expectancy of people in the United States during eight time periods from 1900 to 2010. Look at the top row of the table, labeled "At birth." The average life expectancy of people born at the beginning of the 20th century was about 49 years. Over the course of the 20th century, we observed increasingly longer life expectancies. In the year 2010, people had a life expectancy at birth of 79 years, 30 years longer than they had in 1900, a 61 percent increase in average life expectancy in a little over one century!

How can we know about the life expectancy of people who were born in the year 2010? Not many years have passed to record deaths and life expectancy estimates for this group. The National Center for Health Statistics calculates life expectancy tables based on the number of deaths at each age for a particular year, information from the U.S. Census Bureau about the number of people who are alive at each age, and information from the Medicare program about the likelihood of dying among those aged 85 years and older (Arias, 2007). So whereas the life expectancy for people born in 1900 is based on the actual rates of death experienced by that group over time, the life expectancy projections for people born in 2008 are based on a summary of the death rates in the year 2008 for people at each age.

The next few lines in Table 1.1 give the average remaining years of life for people who have reached an advanced age of 65, 75, or 80 years. For example, a person born in 1900 could expect

Table 1.1 **Average Remaining Lifetime at Various Ages, 1900–2010**

Age	2010	1989	1978	1968	1954	1939–1941	1929–1931	1900–1902
At birth	78.7	75.3	73.3	70.2	69.6	63.6	59.3	49.2
65 years	19.1	17.2	16.3	14.6	14.4	12.8	12.3	11.9
75 years	12.1	10.9	10.4	9.1	9.0	7.6	7.3	7.1
80 years	9.1	8.3	8.1	6.8	6.9	5.7	5.4	5.3

Source: Arias, 2014; U.S. Census Bureau, 1984, 1992, 1997, 2000, 2003.

to live until age 49, but a person who was already 65 in 1900 could expect to live an additional 12 years to age 77. Hazards encountered during the early and middle years of life shorten the average life expectancy at birth. Infant mortality was a major factor in limiting life expectancy at the turn of the 20th century. Furthermore, many women died in childbirth. Respiratory diseases and heart disease were serious threats to life during the middle adult years. If one survived these common killers, chance for a long later life increased.

Over the past 100 years, the U.S. population has changed from one shaped like a pyramid to one shaped more like a rectangle (see FIGURE 1.4 ▶). In 1900 the population had a large number of children and adolescents and relatively fewer adults at each advanced age. In 2010 the population had a relatively smaller percentage of children and adolescents and a relatively larger percentage of adults including a growing percentage of those in advanced old age. These changes have implications for a wide range of social policies regarding education, employment, retirement, health care, and Social Security benefits.

Group Differences in Life Expectancy

Although life expectancy has increased for the population as a whole, significant group differences persist (see Table 1.2). Overall, women outlive men and Hispanics outlive Anglos and African Americans (Arias, 2014). For Anglos without a high school diploma, life expectancy actually declined between 1990 and 2008. Within this subgroup of people without a high school degree, African American women had a longer life expectancy than Anglo women. Although the size of this group of less well-educated whites is decreasing, they appear to be a particularly vulnerable population characterized by high rates of smoking, prescription drug overdoses, obesity, lack of physical exercise, and lack of access to health insurance and health care services (Olshansky et al., 2012).

Gender Differences. Men die at younger ages than women in countries around the world. Since 1979, the gap in life expectancy between males and females has decreased from 7.8 years to 5 years. There are biological, societal, and behavioral explanations for women's longevity advantage, but this discrepancy is not fully understood and is still being investigated. Although more male than female infants are born, more males die at each age than females. Some researchers suggest that estrogen has a protective effect that helps reduce women's risk of heart disease during the childbearing years. Others suggest that because men are physically larger on average than women, their cells must reproduce more often and are at greater risk of exhausting their regenerative potential. Although women suffered higher mortality rates during childbirth at the beginning of the 20th century, the risks associated with childbirth have been substantially reduced. In contrast, men continue to be exposed to more risks associated

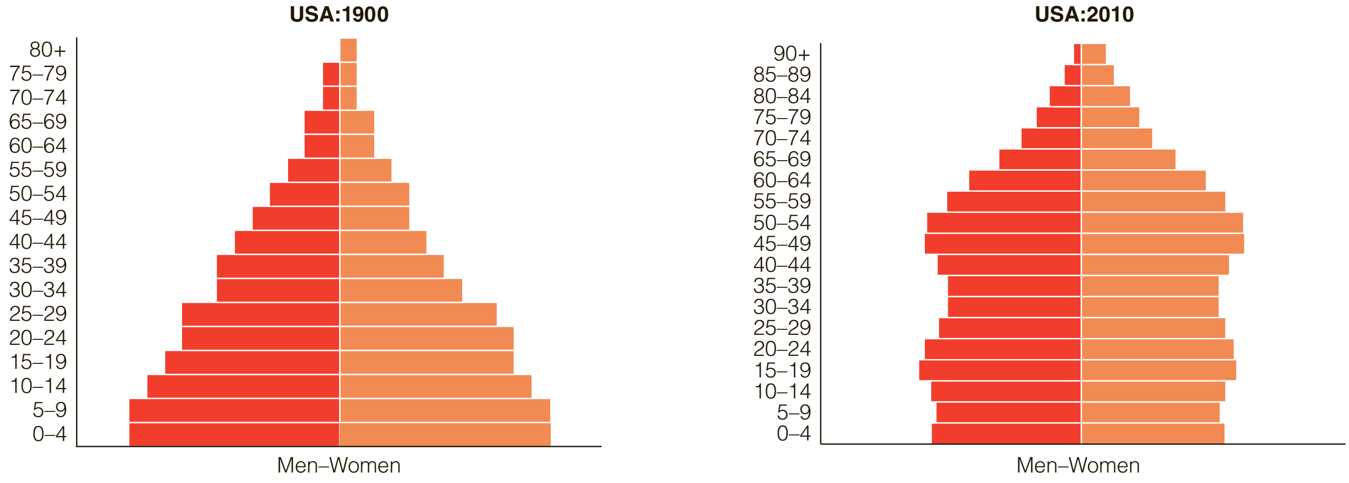

FIGURE 1.4 ▶ U.S. POPULATION PYRAMID: 1900 AND 2010

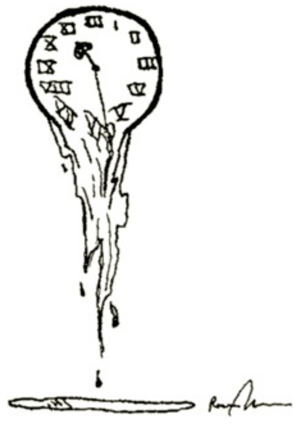
Note: Hispanic is an ethnicity; Hispanics can be of any race.

with physical labor, military service, accidents, and injuries than women. One of the most commonly cited explanations for men's greater risk of heart disease and lung cancer is their more widespread exposure to cigarette smoking. Some researchers suggest that the change in cigarette smoking, both the increase in the number of women who smoke and the reduction in the number of men who smoke, contributes to the narrowing of the longevity advantage of women (Shrestha, 2006).

Racial/Ethnic Differences. In the United States, Hispanic females have the longest life expectancy at birth (83.8 years), and African American males have the shortest (71.8 years) (Arias, 2014). The discrepancy in longevity between the African Americans and other racial/ethnic groups in the United States can be seen in higher rates of death among the African American population from a wide range of causes including cardiovascular diseases, infections, lung disease, diabetes, and traumatic injuries associated with motor vehicle accidents, other accidents, and homicide. These health disparities can be attributed to the confounding of factors, many of which are associated with lifelong exposure to poverty and inadequate access to health care resources. Starting in infancy, more African American babies are born with low birth weight, making them more vulnerable to infant mortality. Poverty is associated with prenatal and infant malnutrition. African American men are more likely to work in hazardous conditions where they may be exposed to toxins and injury, and, at the same time, where employers do not provide health insurance benefits. Across all economic groups, exposure to racial discrimination is itself a lifelong source of stress that can have deleterious psychological and physiological consequences (Arias, 2014; Lewis, Cogburn, & Williams, 2015).

Factors That Contribute to Longevity

We can think of longevity as a product of the interaction of the biological, the psychological, and the societal systems. As an example, improvements in longevity over the past 50 years have been attributed to major reductions in the death rates from diseases of the heart and cerebrovascular diseases (commonly referred to as stroke). These improvements have been brought about by medical advances in diagnosis, emergency treatment, new medicines, and new patterns of care; changes in individual behavior patterns, especially smoking cessation and management of high blood pressure; and changes in social policies that provide greater access to medical resources, especially the introduction of Medicare and Medicaid.



Courtesy of Rachel Newman

Age is relative, as is time. As the life span increases, the way we calculate our sense of maturity and aging changes. How old do you feel you are? In what way does your sense of being old depend on the situation?

Projections of longevity reflect overall changes in the U.S. population. Over the past 50 years, the population has become substantially larger, older, and culturally more diverse (Shrestha & Heisler, 2011). When you try to estimate your own life expectancy, you must consider projections for people in your country, region, and state, and in your age, educational, racial, and sex groups. Furthermore, research with identical twins finds that some components of longevity are genetically guided. People with long-lived ancestors are likely to be long lived themselves. Moreover, individual lifestyle factors have a great impact on longevity. Among these, four of the most powerful influences are education, social integration, diet, and exercise.

Education

Of the many factors that have been studied, education has consistently been linked to health and longevity. Across many societies with many different models of educational opportunity, increases in years of schooling predict added years of life. The benefit of more years of education for longevity has been observed among African Americans and Anglos, men and women. These benefits are explained in part by the relationship of education and wealth. People with more schooling have higher paying jobs. In addition, people with better paying jobs may have greater control over their time and less exposure to dangerous work conditions. Finally, more schooling is associated with better decision-making skills that may influence health care, risk taking, and better self-monitoring of one's health status (Lieras-Muney, 2005; National Center for Health Statistics, 2012).

Social Integration

Social integration has been identified as a factor that influences health and longevity across the life span, from childhood through elderhood (Berkman, Glass, Brissette, & Seeman, 2000; Kolata, 2007; Uchino, Cacciopo, & Kiekolt-Glaser, 1996). Social integration refers to being comfortably involved and connected to meaningful interpersonal associations and friendships and experiencing a sense of belonging. One aspect of social integration that has been linked to improved health and longevity is being in a committed relationship as in marriage, or a civil union. Healthy adults are more likely to find partners who will commit to them. At the same time, couples who are in committed relationships are more likely to be embedded in supportive social networks, to engage in healthy behaviors, and to live longer (Winkelby & Cubbin, 2004).

Diet

A growing body of research emphasizes the potential benefits of a well-balanced diet combined with the strategic use of vitamin and mineral supplements to slow the cellular damage associated with aging and reduce the risks of inflammatory disease (Aronson, 2009; Cannella, Savina & Donini, 2009). The government hosts a website that addresses the relationship of nutrition to specific health concerns, such as diabetes, allergies, cancer, and heart health (see http://www.nutrition.gov/nutrition-and-health-issues).

Exercise

Other research highlights the value of daily activity—even 20 to 30 minutes of exercise and movement—for promoting health and longevity. A modest amount of leisure-time physical activity can add 3 or 4 years to one's life expectancy. Even for people who are obese, those who are physically active have a longer life than those who are inactive (Moore et al., 2012).

As we look to the future, advances in medical technology and treatment coupled with improved support services for older adults can lead to higher standards of living and new levels of functioning in later life. On the other hand, inequities in the distribution of health care services and other societal supports may result in a growing disparity in the quality of later life for various segments of the population.

FURTHER REFLECTION *How long do you think you will live? What are you doing now to increase your chances of living a long, healthy life?*

Explain why education is associated with longevity. What benefits might education provide that could support better health practices and/or access to care?

What are some implications of the increase in life expectancy for social policies? For example, how might the Social Security system, retirement benefits, or community health care services need to change to reflect the needs of an aging population?

CHAPTER SUMMARY

OBJECTIVE 1 Explain the basic assumptions that guide the orientation of the text.

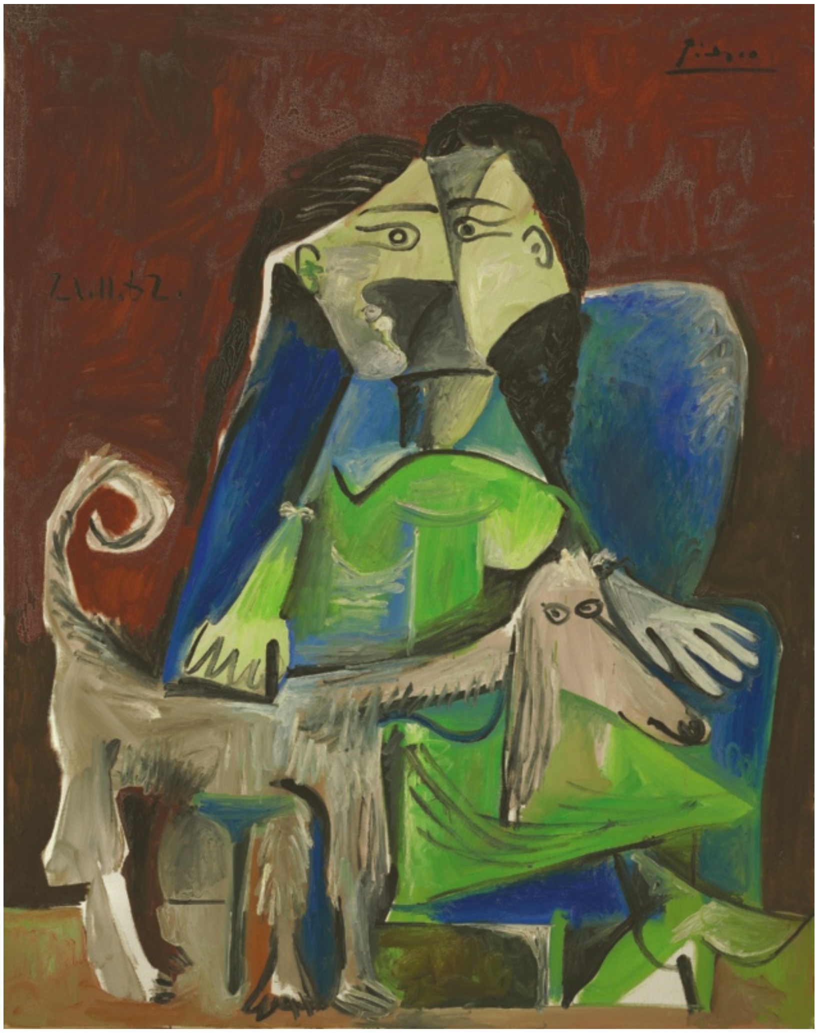
This book presents the story of human development across the life span. The analysis is based on six assumptions: (1) Growth occurs at every period of life, from conception through very old age. (2) Individual lives show continuity and change as they progress through time. (3) We need to understand the whole person because we function in an integrated manner. (4) Every person's behavior must be analyzed in the context of relevant settings and personal relationships. (5) People contribute actively to their development. (6) Diversity is a product of the interaction of the biological, the psychological, and the societal systems.

OBJECTIVE 2 Describe the psychosocial approach to the study of development, including the interrelationship among the biological, psychological, and societal systems.

Psychosocial theory, which provides the organizing framework for the book, emphasizes interaction among the biological, psychological, and societal systems. As a result of maturation and change in each of these systems, individuals' beliefs about themselves and their relationships are modified. Although each life story is unique, we can identify important common patterns, allowing us to anticipate the future and to understand one another.

OBJECTIVE 3 Compare historical changes in life expectancy. Analyze individual and group factors that contribute to longevity.

Demographic information about the life span stimulates thought about one's own life expectancy. In the United States, the average life expectancy increased by more than 50 percent during the 20th century. This dramatic change affects how each of us views our own future. We need to study human development in a constantly changing context. We can never be satisfied that the information from earlier periods will hold true for future generations.



Woman with a Dog; Femme au Chien, 1962 (oil on canvas)/Picasso, Pablo (1881-1973)/CHRISTIES IMAGES/Private Collection/Bridgeman Images

Picasso experiments with strategies to convey the inner and outer worlds of his subjects. Here he shares a glimpse into his private home life using vivid colors and bold outlines. While Jacqueline seems contemplative, their dog seems to be giving us a bit of a smirk. Like abstract art, theories provide ways of understanding behavior by introducing processes and constructs that are not directly observable.

LEARNING OBJECTIVES

1. Explain the concept of theory and discuss how theories contribute to the study of development.
2. Explain the basic concepts of seven major theories and examine the implications of each theory for the study of human development:
    - **2a.** Evolutionary theory
    - **2b.** Psychoanalytic theory
    - **2c.** Cognitive developmental theories
    - **2d.** Theories of learning
    - **2e.** Cultural theory
    - **2f.** Social role theory
    - **2g.** Systems theory

2

MAJOR THEORIES FOR UNDERSTANDING HUMAN DEVELOPMENT

CASE STUDY: Jack Manasky and His Daughter Marilyn

What Is a Theory?
- Requirements of a Theory
- Requirements for Theories of Development

The Theory of Evolution
- Ethology

Chapter Summary

— CASE STUDY Jack Manasky and His Daughter Marilyn —

Jack Manasky has been widowed for 6 years. He still writes letters to his beloved wife Anna, keeping her up to date on the events of his life. In the following letter, Jack writes of a small episode, but a lot is revealed about Jack's life, his sense of self, and his relationship with his adult daughter.

Dear Anna,
I am writing this from a coffee shop. My seat is by the window. Why, you are thinking, am I sitting in a coffee shop when I have a perfectly good house to sit in? Okay, I will tell you.

Marilyn, our dear daughter, may she have a long and wonderful life, this dear child of ours who is no longer a child, decided last month to cure me. Cure me of what, I do not know. I did not ask. One day she came in. A day no different from any other. I was sitting in the living room watching the television news.

Marilyn went into the kitchen to empty her grocery bags. "Dad," she said. "I bought you new coffee. It's decaffeinated." "What does this mean, decaffeinated?" I asked. This I said from my chair; why should I walk into the kitchen? "Unleaded, Dad. You shouldn't be drinking regular coffee. It's a diuretic."

By this time she was standing in the doorway of the kitchen, folding her paper bag. "It means it takes too much water out of you. You're too old for that."

Nu? Decaffeinated? Diuretic? Too much water? Let her do what she wants. What did I care?

I forgot about it. The next day, I got up, I fed the birds, read the newspaper, and drank my coffee. No big deal. But that afternoon, a headache. And what a headache, loud, pounding, I could not think. This was not so new to me. Headaches. They come, they go. But this one, it was different. The next day, it was still with me. And the next day also. Like a black cloud, it filled my head with thunder, everywhere I went.

When Marilyn came on the third day, I remembered. "Marilyn," I said, "this decaffeinated coffee, however you call it, it is killing me."

"Ha, ha," she laughed. "It's not killing you, Dad. It's good for you."

"It's murdering me. Go, buy me some coffee. Or tomorrow you will be pouring this decaffeinated coffee on my grave."

"Dad," she said. "You have a headache? You'll get over it. It's not the decaf that's giving it to you. It's from no caffeine. It'll stop soon." She laughed again, and then she was gone. This is what she does. Comes into my house, checks things off her list, and then disappears.

I sat down. "Okay." I said to the floor. "I will buy my own coffee."

Source: From Starboys by Elissa Goldberg in *Families in Later Life: Connections and Transitions*, by Alexis J. Walker et al., pp. 250–251. Copyright 2001 Pine Forge Press.

You may know people just like Jack Manasky and Marilyn—people with good intentions who have different outlooks on a situation; people who have different goals that guide their actions. And you may have your own personal ideas about why conflicts among parents and their children arise. The purpose of this chapter is to introduce a diverse "basket" of concepts that help to account for the nature of development over the life span. The theories were selected for their significant impact in guiding research and intervention in the field of human development. Many theories presented here continue to be evaluated and challenged as new and competing ideas about human behavior emerge.

First, we consider the role of theory in the study of human development, including a definition of theory and an analysis of what a theory of development is likely to explain. Then we present basic concepts of seven major theories of human development. The *theory of evolution* provides a broad picture of species change over long time periods. Evolutionary theory places the study of individual development in the context of the history of the species. It links humans with other animal species and suggests ways of thinking about key periods in the life span that are critical for species survival. *Psychoanalytic theory* explains the relationship of mental activity to changing needs, wishes, and drives, with a particular focus on the role of sexual and aggressive needs. *Cognitive developmental theory* describes the maturation of capacities for logical thought. *Learning theories*, *cultural theory*, *social role theory*, and *developmental systems theory* each introduce mechanisms that explain how environments guide the content and direction of growth.

In each section, a brief explanation of the theory and a few major constructs are presented, along with an analysis of the theory's contributions to the study of development and links to the psychosocial approach. In subsequent chapters, additional ideas from many of the theories will be presented as they relate to specific topics.

At the end of the explanation of each theory, there is a section called Case Analysis: Using What You Know. These sections present questions that are intended to help you gain insights into the case of Jack Manasky and Marilyn, and to think about it through the lens of each theoretical perspective. By trying to answer these questions, you will begin the process of using what you know to build a conceptual bridge between theory and application. ●

What Is a Theory?

OBJECTIVE 1 Explain the concept of theory and discuss how theories contribute to the study of development.

A **theory** is a logical system of concepts that helps explain observations and contributes to the development of a body of knowledge. We all have our informal, intuitive theories about social life. For example, the adage "The acorn doesn't fall far from the tree" is an informal theory that predicts that children are going to grow up to behave a lot like their parents. However, the idea of a scientific theory is quite different from an informal set of beliefs. In order for a set of ideas to reach the level of a formal scientific theory, it has to be supported by extensive evidence, including systematic experimentation and observation (Zimmerman, 2009). A formal scientific theory is a set of interconnected statements, including assumptions, definitions, and hypotheses that explain and interpret observations. The function of this set of interconnected statements is to describe unobservable structures, mechanisms, or processes and to relate them to one another and to observable events.

In the field of human development, theory is differentiated from research and from facts. The research process, which is described in some detail in the appendix, may be guided by theory. However, the research process is a separate approach to building a knowledge base. For example, Piaget's cognitive developmental theory introduced the idea that through direct interaction with the physical world, infants gradually construct a scheme for the permanent object, an understanding that objects do not cease to exist even when they are out of sight. A growing body of research stimulated by this theory has led to a more differentiated view of what infants know about objects depending on the nature of the task, the kind of response the baby is required to make, and the setting where the baby is being studied. Thus, research often uncovers a more detailed analysis than is presented in the original theoretical formulation.

Facts are distinct from the theories that might try to explain or account for them. For example, in chapter 1, we pointed out that life expectancy at birth in the United States has increased considerably from 1900 to the present. This fact is indisputable. There may be several theories about factors that account for changes in longevity. Each theory might influence the direction of research about longevity. However, these theories do not change the facts.

Major theories reorganize the way we think about and understand the world. Einstein's theory of relativity showed us that matter and energy are two forms of the same thing rather than totally distinct. Freud's theory of psychosexual development showed us that emotional conflicts can be expressed unconsciously through physical symptoms. Once a scientific theory is introduced, it leads the way for testing and elaboration through additional research.

Requirements of a Theory

A formal theory should meet certain requirements. It should be *logical* and *internally consistent*, with no contradictory statements. The hypothetical constructs should be translatable into *testable* hypotheses that can be explored through systematic research. As you read each theory, look for ways that the abstract concepts of the theory can be observed and measured. For example, a theory of learning might suggest that a behavior is more likely to occur when it is followed by a reinforcement. You can test this theory by monitoring a specific behavior, creating a specific reinforcement, and observing whether or not a person performs the behavior more often once the reinforcement has been presented.

The theory should be *parsimonious*, which means that the theory should be simple, relying on as few assumptions, constructs, and propositions as possible while still accurately accounting for the observations. Parsimony is relative. For example, Freud hypothesized that there were five stages of development; Erikson hypothesized that there were eight stages of development. Using the principle of parsimony, one might conclude that Freud's theory is a better one. However, Erikson's theory provides a more differentiated view of adulthood and aging, and, as a result, his theory offers more insight into the process of development over the life span. On the other hand, a theory that suggests 30 or 40 stages of life might be viewed as overly complex and less parsimonious than one that provides a smaller number of integrated periods. Finally, a theory should integrate previous research, and it should deal with a relatively large area of science (P. H. Miller, 2016).

In order to understand a theory, we must answer three questions:

1. **Which phenomena is the theory trying to explain?** Understanding the focus of the theory helps to identify its **range of applicability**. There are many different types of theories, each with its own range of applicability. For example, there are theories of personality, learning, decision making, conflict resolution, group dynamics, leadership, counseling, social work practice, and family formation. Just within the field of human development, there are many theories including those that account for language development, theories that focus on emotional bonds between parents and their children, and theories that address processes of change from one generation to the next. Although principles from one theory may have relevance to another area of knowledge, a theory is evaluated in terms of the behavior it was originally intended to explain.
2. **What assumptions does the theory make?** Assumptions are the guiding premises underlying the logic of a theory. In order to evaluate a theory, you must first understand what its assumptions are. Charles Darwin assumed that lower life forms "progress" to higher forms in the process of evolution. Freud assumed that all behavior is motivated and that the unconscious is a "storehouse" of motives and wishes. The assumptions of any theory may be challenged or modified over time. For example, we do not necessarily think of a progression from lower to higher life forms as Darwin discussed them. Life forms have unique adaptive capacities—owls have exceptional night vision; bats have unusual hearing; humans have unique cognitive capacities. In Darwin's time, humans were thought to be a higher life form; now we recognize the diverse adaptive advantages of varied species. Assumptions may be influenced by the following:
    The cultural context that dominates the theorist's period of history
    The sample of observations from which the theorist has drawn inferences
    The current knowledge of the field
    The intellectual capacities, values, religion, and education of the theorist
3. **What does the theory predict?** Theories add new levels of understanding by suggesting causal relationships, unifying diverse observations, and identifying the importance of events that may have gone unnoticed. Theories of human development offer

explanations regarding the origins and functions of human behavior, predictions about changes that can be expected in behavior from one period of life to the next, and hypotheses about the mechanisms or processes that account for change.

Requirements for Theories of Development

A theory of development usually helps explain how people change and grow over time, as well as how to account for continuity. We expect a theory of human development to provide explanations for six questions:

1. **What is the *direction* of change over the life span?**
   We assume that there is a direction to development, that it is not random. Development is not the same as changing one's hairstyle or deciding one day to play tennis and the next day to play soccer. Theories of development offer some big ideas about maturity and shed light on important ways in which thought, self-understanding, the capacity for social relationships, and the capacity for adaptation become increasingly complex and integrated through the course of life. Some theories suggest that change takes place in a sequence of stages or qualitatively distinct periods of life. Other theories suggest processes that account for gradual change or highlight significant events that result in transitions at various points in life.
2. **What are the *mechanisms* that account for growth from conception through old age? Do these mechanisms vary across the life span?**
   Theories of development identify the processes or experiences that bring about systematic change. In this chapter and throughout the text, we will present and explain a variety of mechanisms theorists offer for how growth and development occur. Some theories emphasize a biologically based, genetically guided plan for development. Others emphasize the role of the environment in shaping behavior and providing roles or settings that support new levels of functioning. Still other theories emphasize the ongoing interaction of biological and environmental factors, characterizing development as a process of adaptive self-organization.
3. **How relevant are *early experiences* for later development?**
   Theories of development offer different ideas about the significance of early experiences for the psychological and behavioral organization of later periods of life. Some theories suggest that incidents from infancy and childhood play a powerful role in guiding the direction of development well into adulthood. Other theories emphasize the influence of contemporary events in guiding development by viewing the person as continuously adapting to new demands and new opportunities.

   One important question that emerges in the study of development is the degree to which individuals can be characterized as **resilient** in the face of early stresses or deprivation. Current work in cognitive neuroscience suggests that there is a high degree of plasticity in the human brain. In cases of injury, one area of the brain can reorganize to take over functions of another area. Plasticity is observed across the life span, well into later life. The human brain has evolved to have a great degree of flexibility, being able to adapt to a wide range of family, cultural, language, and environmental conditions. At the same time, there is a growing literature about the risks of early exposure to harsh parenting and the long-term consequences of these early negative experiences. This research suggests that events that unfold early in life may set a person on a trajectory that intensifies certain ways of thinking and feeling and narrows the options for recovery.
4. **How do *physical, cognitive, emotional, and social* functions interact?**
   Most theories of human development focus on a specific domain such as cognition, learning, social relationships, or the expression and management of emotions. However, they also consider the interplay of other domains. For example, according to social learning theory, feelings of tension or anxiety in the learning situation can influence a person's confidence about whether a new skill can be mastered. According to cognitive theory, emotions can contribute to the person's attention and motivation to persist in seeking the solution to a problem.
5. **How do the *environmental* and *social contexts* affect individual development?**
   Individuals develop in social and physical **contexts**. Theories of human development differ in the ways they conceptualize settings and relationships, and in which aspects of these contexts are especially important in shaping the directions of growth. Should we focus on interactions with mother as context? Father? Both parents? Siblings? Friends? Spouse? School? Work? The physical environment of home or neighborhood? How do social constructions, including social class, race, ethnicity, and religion, become integrated into a person's life story? How and in what ways do they matter?

   Research on the interaction of environment and genetic predisposition illustrates the complexity of these questions. For example, some genes are highly responsive to environmental influences. A serotonin transporter gene, *5 HTTLPR*, has a short and long allele. Earlier studies had linked the gene to vulnerability to depression. Recent studies have shown that individuals who have two short alleles are more vulnerable to depression as young adults if they grew up in a cold, emotionally distant, or harsh family environment. Individuals with this same genetic makeup are less likely than others to experience depression if they grew up in a warm, nurturing, and supportive environment (Taylor et al., 2006). This kind of research illustrates the need for theories of development to consider the interactions of biological factors and environmental conditions that may be relevant at particular periods of life.

6. **What factors are likely to place the person *at risk* at specific periods of the life span?**
   Although humans have an enormous capacity for adaptation, some combination of conditions is likely to impede optimal growth. Each theory of human development provides constructs that help us understand the nature of risks as well as predictions about conditions that increase risks. Some theories also offer differentiated views of risk across the life span or at different critical life transitions.

Each of the seven theories reviewed in this chapter provides concepts that can be applied to these questions. No single theory is currently accepted as the unifying explanation for the process of development; however, taken as a whole they offer concepts that guide research, intervention, and programming. As you read each theory, keep in mind the assumption that development is a product of the interaction of the biological, the psychological, and the societal systems. Try to identify the ways each theory incorporates these systems in its approach to explaining processes of continuity and change. Consider how you might apply these concepts. For example, imagine that you had to explain development to a new parent. What mechanisms or processes do the seven theories offer to explain how children grow up and change from infancy to adulthood? What ideas from each of the theories might be most useful in supporting the parenting process?

The Theory of Evolution

OBJECTIVE 2a Explain the basic concepts of the theory of evolution and examine its implications for the study of human development.

The theory of evolution focuses on how diverse and increasingly complex life forms come to exist. The law of **natural selection** explains how those individuals who are best suited to the immediate features of their environment are most likely to survive and reproduce. Over generations, species gradually change to respond to changing environmental conditions. Darwin referred to this process as **adaptation** (Darwin, 1859/1979).

The phrase "survival of the fittest" is sometimes associated with Darwin's theory of evolution. A common interpretation of this expression is that those who are the strongest or most powerful will survive. In fact, the term "fitness" has a more nuanced meaning—it refers to the idea of reproductive success.

Reproductive success, called **fitness**, varies among members of a species (Archer, 1991). Every species produces more offspring than can survive to reproduce because of limitations of the food supply and natural dangers. Darwin observed that there was quite a bit of variability among members of the same species in any given location. Some individuals are better suited to their immediate environment than others and, thus, are more likely to survive, mate, and produce offspring. These offspring are more likely to have characteristics appropriate for that location. Over time, those members of a species that have a selective advantage are more likely to survive and reproduce, thus passing their genetic characteristics on to future generations.

If the environment changes (e.g., in climate), only certain variations of organisms will survive. Failure to adapt will lead to species **extinction**. In the context of changing environmental conditions, the fact that there is variability within a species ensures the species will continue or develop into new forms. Evolutionary change takes place slowly and incrementally as individual organisms adapt and populations with similar adaptive characteristics come to dominate an environment or **ecological niche**.

Darwin described two aspects of evolution (Mayr, 1991). One is the gradual change within a species over time from earlier to later forms. For example, even though they are the same species, chimpanzees alive today are not identical to the chimpanzees that lived thousands of years ago. The second form of evolution involves the breaking away from an earlier evolutionary lineage and the establishment of a new species. This is the process of **speciation** that contributes to biological diversity. For example, some combination of events led to the separation of the hominids from Homo erectus to Homo sapiens thousands of years ago (Stringer, 2012).

The concept of **inclusive fitness** suggests that a characteristic can be selected if the genes are passed along to the next generation by promoting the survival and reproductive success of others who carry those genes (Hamilton, 1964). In human groups, behaviors that support one's family members or that make it possible for one's kin to be more attractive in the mating process would be considered examples of inclusive fitness. This concept highlights the adaptive advantage of supportive kin networks that selectively direct their resources toward members of their family, kinship network, tribe, or ethnic group.

Advances in the field of genetics coupled with advances in neuroscience have begun to shed new light on the evolutionary process. By analyzing the human genome, one can better compare humans to primates and other mammals, leading to a clearer understanding of the likely points at which the brains of various species diverged. For example, in an analysis of the Y chromosome in a variety of populations, researchers have estimated that all humans alive today are descendants of a small group of about 4,000 men and women who left Africa less than 100,000 years ago and settled throughout the rest of the world. These humans carried the *FOXP2* gene that supports advanced language capacity and other symbolic and representational arts (Drake, 2015; Enard et al., 2002; Underhill et al., 2000).

Ethology

Two subspecialties that have emerged from evolutionary theory are *ethology* and *evolutionary psychology*. **Ethology** is the comparative study of behavior in its social contexts in order to understand the immediate causes of these behaviors and their adaptive significance. Ethologists focus on describing the unique adaptive behaviors of specific species, such as mating, caregiving, play, or strategies for obtaining resources. They are especially interested in behaviors that appear to be spontaneous and that provide some type of adaptive advantage. An example is the infant's smile. Smiles occur early in the postnatal period. They function as a powerful signal that evokes a caregiving response. Over time, the infant's smile takes on a more complex meaning within the social context. Yet smiling begins as an unlearned behavior that has important survival value in producing caregiving (Fogel et al., 2006).

Through comparisons among species, the study of the conditions that evoke and maintain adaptive behaviors helps to clarify the role of behavior in the long-term survival of the species. Many areas of human behavior that are functionally relevant to the fitness of individuals and groups are potential targets of study in the field of human ethology (Charlesworth, 1992; Eibl-Eibesfeldt, 2007). They include:

Reproductive strategies, such as having few or many sex partners
Infant immaturity requiring prolonged care
Infant–caregiver attachment
Parent–child conflicts
Sibling rivalry
Peer group formation and functions, especially cooperation, competition, dominance, and submission
Peer bonding and mate selection
Helping behaviors and altruism
Learning as adaptive behavior
Individual creation and modification of the environment
Elaboration of rites, rituals, and religions

Evolutionary Psychology

Evolutionary psychology is the study of the evolutionary origins of mental structures, emotions, and social behavior. Whereas ethology focuses on analyzing adaptive behavior patterns across species, evolutionary psychology draws on principles of evolution to understand the human mind. Cosmides and Tooby (1997) stated: "The mind is a set of information processing machines that were designed by natural selection to solve adaptive problems faced by our hunter-gatherer ancestors." This focus takes us to a time when humans lived in small, nomadic groups, traveling from place to place to find sources of food and trying to protect themselves from the dangers of predatory animals, weather, illness, and other humans. This way of life existed for more than 2 million years, during which time various human species (along with their human minds) emerged. From this perspective, the mind is highly adapted to solve the problems faced by these human ancestors, but it may not be well adapted to solve the new problems that have emerged in our recent industrial and postindustrial way of life.

From an evolutionary perspective, any behavior can be assessed by asking a few basic questions: What behavior is necessary to achieve a goal? How much energy is needed to achieve the goal? When should the organism stop the activity? What should the organism do next? These questions suggest that the organism has to recognize the nature of a problem, apply the best "tool" needed to solve the problem, and be mindful of the extent to which efforts to achieve a goal are using up resources (Neese, 2001). There are start-up costs to beginning any new behavior. Once a behavior has been started, the organism has to assess how hard and how long to persist at the task. There is risk in putting too much energy into one problem and ignoring other important tasks.

The work of David Buss on mating strategies provides an example of the approach that evolutionary psychology takes to understanding human behavior. According to evolutionary theory, one of the key components of fitness is the mating process.

> Successful mating requires solutions of a number of difficult adaptive problems. These include selecting a fertile mate, out-competing same-sex rivals in attracting a mate, fending off mate poachers (those who try to lure one's mate away), preventing the mate from leaving, and engaging in all of the necessarily sexual and social behaviors required for successful conception to take place. (Buss, 2006, p. 239)

The work of John and Stephanie Cacioppo focuses on the adaptive value of social connections (Cacioppo, J., & Cacioppo, S., 2012; Cacioppo, S., & Cacioppo, J., 2012). Human beings are social animals whose evolutionary survival depended on being well integrated into a social group. The human brain is organized to monitor social connections and to detect inadequate social bonds as potential sources of threat. When people perceive that their social connections are inadequate, they experience loneliness. And loneliness has significant, measureable consequences including sleep disturbances, longer time for wound healing, difficulty

mark higgins/Shutterstock.com

From an evolutionary perspective, the attachment behavioral system is central to the offspring's survival. Adults have strategies for monitoring and protecting their young, and infants have capacities for alerting their caregivers when they are frightened or upset. What behaviors in human infant–mother pairs help them stay connected in times of distress?

with communication, and depression. Perceptions of being lonely may be especially strong when relationships that are expected to be supportive, such as relationships between marital partners, parents and children, or close friends, become strained or distant.

Implications for Human Development

Darwin's theory of evolution by means of natural selection provided the foundational theoretical framework for much of American psychology through its influences on William James, G. Stanley Hall, John Dewey, and their students. An underlying premise of natural selection is that new or emerging capacities are retained as a result of their adaptive value. This perspective was elaborated by William James in defense of consciousness itself. James argued that consciousness evolved and has been preserved among humans because it contributes positively to the chances of survival. By being able to set a goal, plan a course of action, assess progress toward that goal, and modify actions as needed, consciousness and its corollary, free will, increase the ability of human beings to adapt effectively to whatever environments or environmental changes they encounter (Dewey, 1896; Green, 2009; James, 1890).

With its focus on reproductive success, evolutionary theory highlights three phases of the life span: (1) healthy growth and development leading up to the reproductive period; (2) success in mating and the conception of offspring; and (3) the ability to parent offspring so they can survive, reach reproductive age, and bear offspring of their own (Charlesworth, 1992).

Humans are most vulnerable during infancy and childhood. Children require nurture and care in order to survive to reproductive age. Biological capacities and the environments in which they can be expressed operate together to produce behavior. A genetic plan, shaped through hundreds of generations, guides infants' predispositions, capacities, and sensitivities. Evolutionary theory points out that infants come into the world with a range of innate capacities and potentials. They are able to establish social contact, organize information, and recognize and communicate their needs.

The genetic potential of human infants is much greater than the behaviors actually exhibited in any particular cultural context. Infants have to be able to respond to the specific language environment, diet, parenting behaviors, and other physical and social contexts in which they are born. Particular environments are likely to take advantage of certain genetic predispositions and not others. Infants must adapt to a variety of environmental conditions including differences in the quality of parenting, adequacy of resources, and competition for resources with other siblings. Childhood experiences shape the future of the human species by providing the context for the establishment of attachments, meaningful social competence, and problem-solving capacities. These in turn have a bearing on an individual's behavior in adulthood—particularly the ability to form intimate relationships and to parent one's offspring.

In adolescence and adulthood, the evolutionary focus shifts to emerging reproductive capacities—the ability to find a mate, to reproduce, and to rear one's young so they can reach their own reproductive age. With advanced age, the forces of selection weaken. Because early humans died at a relatively young age due to predators, diseases, and environmental hazards, the selective advantage of characteristics that might be noticeable in later life was not preserved. As a result, the genome does not guide the direction of development to preserve high levels of functioning in later life as it so clearly does in infancy, childhood, and the transition through puberty to reproductive adulthood (Baltes, 1997). More rests on culture, lifestyle, and social resources to support successful aging.

The evolutionary perspective draws attention to the interconnection between an individual's life history and the long-range history of the species. Principles of natural selection operate slowly over generations. However, the reproductive success of individuals over the course of their own life span determines whether their genetic material continues to be represented in the larger population. The evolutionary perspective also directs attention to the importance of variability for a species' survival. These differences help explain how the human species adapts successfully across a wide variety of environmental conditions.

Links to the Psychosocial Approach

The psychosocial approach translates the idea of species adaptation to the individual level. Individuals encounter a necessary developmental struggle between their own traits and capacities and the requirements and demands of the environment. Each generation within a society faces similar challenges to cycle critical resources to the young, form enduring social bonds that will result in a reproductive environment, nurture competence and a capacity for caring in the new generation of adults, and inspire younger generations with hope and anticipation about the prospects of growing old. Within cultural groups, rites and rituals serve to protect and preserve resources, direct the rearing of children, and assist individuals through key transitions. Groups that adapt successfully are those that effectively sustain their resources so they can be available for future generations, integrate new members, and pass along information that will help individuals cope with future challenges. For a list of the key concepts of evolutionary theory, see Table 2.1.

CASE ANALYSIS Using What You Know

1. The case of Jack Manasky and Marilyn focuses on the life and behaviors of someone in the stage of elderhood. What is the adaptive benefit of longevity? What does survival into elderhood contribute to species survival?
2. What aspects of fitness are illustrated in the case of Jack Manasky and Marilyn? How can evolutionary theory account for Marilyn's motivation to care for her aging father?
3. What adaptive problems is Jack dealing with? What are his coping strategies? Does Marilyn understand Jack's problem-solving efforts? Why or why not?

Psychoanalytic Theory

OBJECTIVE 2b Explain the basic concepts of psychoanalytic theory and examine its implications for the study of human development.

Evolutionary theory emphasizes the importance of reproductive functions as they contribute to fitness and long-term species adaptation. In contrast, psychoanalytic theory focuses on the impact of sexual and aggressive drives on the individual's psychological functioning. It distinguishes between the impact of drives on mental activity and their effect on reproductive functions. The theory assumes that very young children have strong sexual and aggressive drives that find unique modes of expression through successive stages of psychosexual development. Throughout childhood, adolescence, and adult life, sexual and aggressive drives operate to direct aspects of one's fantasies, self-concept, problem-solving strategies, and social interactions.

A unique feature of psychoanalytic theory is the importance placed on childhood experiences for shaping adult thoughts and behavior. The theory focuses on both normative and pathological patterns of growth and development that result from the socialization pressures that act on biologically based drives. The theory highlights the relevance of certain primary social ties, especially the mother–child and father–child relationships, for their roles in determining the expression and gratification of needs and the internalization of moral standards. Many contributions of psychoanalytic theory continue to influence the study of development and approaches to therapeutic interventions.

Five Components of Psychoanalytic Theory

Five components of psychoanalytic theory are reviewed in the chapter: (1) motivation and behavior, (2) domains of consciousness, (3) the structure of personality, (4) stages of development, and (5) defense mechanisms. Two extensions of the theory, object relations theory and ego psychology, are briefly explained.

Motivation and Behavior

Freud assumed that all behavior (except that resulting from fatigue) is motivated. He thought that all behavior has meaning; it does not occur randomly or without purpose. A related assumption of psychoanalytic theory is that there is an area of the mind called the **unconscious** that is a storehouse of powerful, primitive motives of which the person is unaware. Unconscious as well as conscious motives may motivate behavior simultaneously. Thus, behaviors that may appear to be somewhat unusual or extremely intense are described as **multiply determined**—that is, a single behavior expresses many motives, some of which the person can recognize and control and others that are guided by unconscious thought.

Freud's analysis of development and mental illness are derived from his understanding of the ways that sexual and aggressive drives press for expression and are inhibited or given various outlets in thoughts, dreams, behaviors, and symptoms. The term *drive* is sometimes referred to as psychic energy, tension, instincts, or *libido*. **Drives** can be thought of as sexual and aggressive forces that have a biological or somatic origin—they are a result of some metabolic functions but are also intimately linked to psychological processes. The energy behind the drives builds up as it seeks satisfaction. The psychic energy that is embodied in these drives can be expressed in a variety of ways, but the energy itself will not be destroyed.

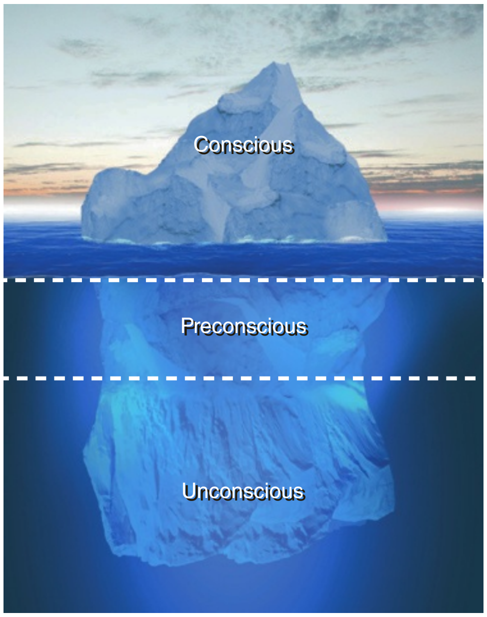
Drives have a power or force along a continuum from mild to strong. Drives have an aim—a desire to be satisfied. When possible, drives are satisfied immediately to reduce tension and achieve a state of equilibrium. Drives have an object—a person or thing that allows the drive to achieve its aim. The object of the drive is closely linked to the specific environment in which the child functions.

Imagine that Kevin, who is three, comes home from preschool. The first thing his mother says is, "Kevin, do you need to go potty?" Kevin says "No," and starts to play with his train set. A half hour later, Kevin's mother says, "Kevin, you need to go potty and wash up before dinner." Kevin yells, "No, I'm busy with trains; I can go later. I know how to go when I need to." According to the theory, Kevin takes pleasure in holding on or letting go by controlling his anal functions. His drive to control these body experiences is strong. Now that he has his toilet habits pretty well developed, Kevin gets pleasure from knowing that he can enjoy letting go when he wants to. Having his mother repeatedly remind him about toileting competes with his own drive for physical pleasure associated with elimination. When he yells at her, and tells her "NO!" he gains some expression of his aggressive drives. In order to understand how drives are satisfied, one must have a concrete understanding of the social and physical resources that are available to a child at a specific developmental period. With maturity, a person becomes able to delay satisfaction of the drives and finds increasingly flexible and socially appropriate ways to achieve satisfaction.

Domains of Consciousness

Freud thought the human mind was like an iceberg (see FIGURE 2.1 ▶). **Conscious processes** are the tip that protrudes out of the water; they make up only a small part of the mind. Our conscious thoughts are fleeting. We can have only a few of them at any one time. As soon as energy is diverted from a thought or image, it disappears from consciousness.

The **preconscious** is analogous to the part of the iceberg near the waterline. Material in the preconscious can be made conscious



© Cengage

FIGURE 2.1 ▶ TOPOGRAPHY OF MENTAL ACTIVITY: DOMAINS OF CONSCIOUSNESS

if attention is directed to it. Preconscious thoughts are readily accessible to consciousness through focused attention. You may not be thinking about your hometown or favorite desserts right now, but if someone were to ask you about either of them you could readily recall and discuss them.

The unconscious, like the rest of the iceberg, is hidden from view. It is a vast network of content and processes that are actively barred from consciousness. Freud hypothesized that the content of the unconscious, including wishes, fears, impulses, and repressed memories, plays a major role in guiding behavior even though we cannot explain the connections consciously. Through certain techniques used in psychotherapy, the link between unconscious wishes and fears and overt behaviors can often be established.

Three Structures of Personality

Freud (1933/1964) described three components of personality: the id, the ego, and the superego. Freud suggested a developmental progression in which id exists alone at birth, ego emerges during infancy, and the superego takes shape in early childhood.

Id. The **id,** including instincts and impulses, is the primary source of psychic energy, and exists from birth. Freud believed that newborn infants' mental processes were comprised completely of id impulses and that the ego and superego emerged later, drawing their energy from the id.

The id expresses its demands according to the **pleasure principle**: People are motivated to seek pleasure and avoid pain. Its rule is to achieve the immediate satisfaction of impulses and to discharge energy without regard to the feelings of others. When you lie to a friend to protect your image, or when you cut ahead of people in line so you won't have to wait, you are operating according to the pleasure principle.

The logic of the id is called **primary process thought**. It is characterized by a lack of concern for the constraints of reality. In primary process thought, there are no negatives. Everything is yes. There is no time. Nothing happens in the past or in the future. Everything is now. Symbolism becomes flexible. One object may symbolize many things, and many different objects may mean the same thing. Many male faces can all represent the father. The image of a house may be a symbol for one's mother, a lover, or the female genitalia as well as for a house.

Ego. **Ego** is a term that has two related meanings. One is the idea of ego as a person's self, including one's physical self, self-concept, self-esteem, and mental representations of the self in relation to others. This sense of ego emerges as psychic energy and is directed toward the self—a process that is sometimes called **primary narcissism**. The idea is that the sense of self is born out of self-love, an enthusiasm and excitement for one's body, one's experiences, and one's emerging sense of agency. The second idea of ego refers to all mental functions that have to do with the person's relation to the environment. It includes a multitude of cognitive processes such as perception, learning, memory, judgment, self-awareness, and language skills that allow a person to take in information, process it, assess its implications, and select a course of action. Freud thought the ego begins to develop in the first 6 or 8 months of life and is well established by the age of 2 or 3.

The ego operates according to the **reality principle**. Under this principle, the ego protects the person by waiting to gratify id impulses until a socially acceptable form of expression or gratification can be found. In the ego, primary process thought becomes subordinated to a more reality-oriented thinking, called **secondary process thought**, the kind of logical, sequential thinking that we usually mean when we discuss thinking. It allows people to plan and act in order to engage the world and to achieve gratification in personally and socially acceptable ways. It enables people to delay gratification. It helps people assess plans by examining whether they will really work.

Superego. The **superego** includes both a punishing and a rewarding function. The **conscience** includes ideas about which behaviors and thoughts are improper, unacceptable, and wrong. It carries out the punishing function. The **ego ideal**, which includes ideas about what behaviors and thoughts are admirable, acceptable, and worthy of praise, carries out the rewarding function. Because it is formed during early childhood, the superego tends to be harsh and unrealistic in its demands. It is often just as illogical and unrelenting in its search for proper behavior as the id is in its search for pleasure. When a child thinks about behaving in a morally unacceptable way, the superego sends a warning by producing feelings of anxiety and guilt.

Freud thought that the superego does not begin to develop until the age of 5 or 6 and is probably not firmly established until several years later. Other theorists have suggested that the roots of the superego emerge in infancy as the child becomes differentiated from the caregiver and aware of the possibility of disrupting the close bond with this loving object (Klein, 1948).

What Is the Relationship of Id, Ego, and Superego? Ego processes work toward satisfying id impulses through thoughts and actions without generating strong feelings of guilt in the superego. In one sense, ego processes serve both the id and the superego, striving to provide gratification, but in morally and socially acceptable ways. In another sense, ego is the executive of personality. The strength of the ego determines the person's effectiveness in meeting needs, handling the demands of the superego, and dealing with the demands of reality. If the ego is strong and can establish a good balance among id, superego, and environmental demands, the person is satisfied and free from immobilizing guilt and feelings of worthlessness.

When id and superego are stronger than the ego, the person may be tossed and turned psychologically by strong desires for pleasure and strong constraints against attaining those desires. When environmental demands are strong and the ego is weak, a person may also be overwhelmed. According to psychoanalytic theory, it is the breakdown of the ego that leads to mental disorder.

Stages of Development

According to psychoanalytic theory, the most significant developments in personality take place during five life stages from infancy through adolescence with the primary emphasis given to the first 5 or 6 years of life. During those years, the essential pattern for expressing and controlling impulses is established. Later life serves primarily to uncover new modes of gratification and new sources of frustration.

The five psychosexual stages are the oral, anal, phallic, latent, and genital stages. These stages reflect the emphasis on **sexuality** as a driving force. During the **oral stage**, in the first year of life, the mouth is the site of sexual and aggressive gratification. Babies use their mouths to explore the environment, to express tension, and to experience pleasure. As infants learn to delay gratification, they become aware of the distinction between the self and others. With this awareness comes the realization that all wishes cannot be satisfied.

In the **anal stage**, during the second year of life, the anus is the most sexualized body part. With the development of the sphincter muscles, a child learns to expel or withhold feces at will. The conflict at this stage focuses on the subordination of the child's will to the demands of the culture (via parents) for appropriate toilet habits.

The **phallic stage** begins during the third year of life and may last until the child is 6. It is a period of heightened genital sensitivity in the absence of the hormonal changes that accompany puberty. At this stage, children direct sexualized activity toward both sexes and engage in self-stimulation. This is the stage during which the Oedipal or Electra complex is observed.

The **Oedipal complex** in boys and the **Electra complex** in girls result from ambivalence surrounding heightened sexuality. The child has a strong, sexualized attraction to the parent of the opposite sex, and the same-sex parent becomes a fantasized rival. The child may desire to have the exclusive attention of one parent and may fantasize that the other parent will leave, or perhaps die. At the same time, the child fears that amorous overtures toward the desired parent may result in hostility or retribution from the parent of the same sex. The child also worries that this beloved, same-sex parent will withdraw love. Parental threats intended to prevent the child from masturbating and fantasies of the possibility of castration or bodily mutilation may add to the child's fears that sexualized fantasies are going to result in **punishment** or withdrawal of love.

In a successful resolution of the Oedipal or Electra conflict, the superego emerges as a strong structure that aids the ego in controlling unacceptable impulses. Through a process of **identification** with one's parents' moral and ethical values, the child achieves a new level of autonomy and at the same time receives the admiration and approval of both parents who see the child as moving in the direction of maturity and self-control. Most of the intense and painful conflicts of this period are repressed, and the ego emerges with a new degree of self-esteem and confidence about the child's place in the family structure.

Once the Oedipal or Electra conflict is resolved, the child enters a period of **latency**. During this stage, which lasts from about 7 years until puberty, no new significant conflicts or impulses arise. The primary personality development during this period is the maturation of the ego.

A final stage of development begins with the onset of puberty: the **genital stage**. During this period, the person finds ways of satisfying sexual impulses in mature, dyadic relationships. Adolescence brings about a reawakening of Oedipal or Electra conflicts and a reworking of earlier childhood identifications. Freud explained the tension of adolescence as the result of the sexual threat that the mature adolescent poses to the family unit. In an effort to avoid this threat, adolescents may withdraw from their families or temporarily devalue their parents. With the formation of a romantic attachment to someone outside the family, the threat of intimacy between young people and their parents diminishes. At the end of adolescence, a more autonomous relationship with one's parents becomes possible.

Freud believed that the psychological conflicts that arise during adolescence and adulthood result from a failure to satisfy or express specific childhood wishes. At any of the childhood stages, sexualized impulses may have been so frustrated or overindulged that the person continues to seek their gratification at later stages of life. The term **fixation** refers to continued use of pleasure-seeking or anxiety- reducing behaviors appropriate to an earlier stage of development. Because no person can possibly satisfy all wishes at every life stage, normal development depends on the ability to channel the energy from those impulses into activities that either symbolize the impulses or express them in a socially acceptable form. This process is called **sublimation**. During adolescence and early adulthood, patterns of impulse expression, fixation, and sublimation crystallize into a life orientation. From this point on, the content of the id, the regulating functions of the superego, and the executive functions of the ego rework the struggles of childhood through repeated episodes of engagement, conflict, and impulse gratification or frustration.

Defense Mechanisms

Much of the ego's work involves mediating the conflicts between the id's demands for gratification and the superego's demands for good behavior. This work is conducted outside the person's awareness. When unconscious conflicts threaten to break through into consciousness, the person experiences anxiety. If the ego functions effectively, it pushes these conflicts into the unconscious, thereby protecting the person from unpleasant emotions.

When the ego is unable to resolve these conflicts, a person may experience intense anxiety, and symptoms may emerge. A person who feels a desire that is thought to be very "bad," such as an unconscious wish to harm a parent or to be sexually intimate with a sibling, may experience anxiety without recognizing its source. The unexpressed drive continues to seek gratification. The unpleasant emotional state may preoccupy the person and make it difficult to handle the normal demands of day-to-day life.

Defense mechanisms protect the person from anxiety so that effective functioning can be preserved. They distort, substitute, or completely block out the source of the conflict. They are usually initiated unconsciously. The defense mechanism used depends on a person's age and the intensity of the perceived threat. Younger children tend to use denial and repression (pushing thoughts from awareness). A more diverse set of defenses, requiring greater cognitive complexity, becomes available in the course of development. In situations of greatest threat, denial is often the initial defense used, regardless of age.

According to Freud, the basic defense mechanism is **repression**, a process whereby unacceptable impulses are pushed into the unconscious. With unacceptable thoughts and impulses far from awareness, the person is protected from uncomfortable feelings of anxiety and may devote the remaining psychic energy to interchange with the interpersonal and physical environments. This defensive strategy has two major costs. First, it takes energy to continue to protect the conscious mind from these thoughts, thereby reducing the amount of mental energy available to cope with other daily demands. Second, if too many thoughts and feelings are relegated to repression, the person loses the use of the emotional system as a means of monitoring and evaluating reality.

Defense mechanisms not only reduce anxiety but also may lead to positive social outcomes. Physicians who use isolation may be able to function effectively because they are able to apply their knowledge without being hindered by their feelings. Children who rationalize defeat may be able to protect their self-esteem by viewing themselves favorably. The child who projects angry feelings onto someone else may find that this technique stimulates a competitive orientation that enhances performance.

Regression is an interesting example of a defense mechanism when considered from a developmental perspective. Regression means that a person (child or adult) reverts to an earlier form of drive satisfaction, immature forms of relationships with others, lower moral standards, or more simplistic ways of thinking and solving problems. Regression can serve ego development if it is not met with extreme disapproval (Blos, 1967; A. Freud, 1965). Sometimes it is necessary to return to an earlier mode of functioning in order to resolve conflicts that were inadequately resolved at that time, or to engage in a kind of playful childishness in order to achieve a new level of mastery. Most obviously, in the creative process, a certain amount of regressive fantasy can unlock possible associations that make sense according to primary process thinking but are censored in secondary process thinking.

Object Relations Theory

Object relations theory is an adaptation of psychoanalytic theory that places less emphasis on aggression and sexuality and more emphasis on human relationships as the primary motivational force in life (Kernberg, 2005). The term *object* means a person or thing that allows the drive to achieve its aim. Object relations theory stresses that humans have basic needs for connection, contact, and meaningful interpersonal relationships throughout life (Borden, 2000; Safran, 2012). In this view, infants have a very limited sense of self. The self is formed in relationships with primary objects, especially the mother, father, or other close and continuous caregivers.

Margaret Mahler (Mahler & Furer, 1968; Mahler, Pine, & Bergman, 1975) described the self as taking shape in three stages over the first 2 years of life. At first, the infant simply enjoys the isolated events of the caregiving relationship. In this context, drives are satisfied and a sense of frustration is followed by a sense of satisfaction when needs are met. In the second phase, infants enjoy engaging in more rhythmic interactions with the primary caregiver, initiating interactions that are social and not necessarily focused solely around meeting basic needs. In the final stage, a process of separation and individuation occurs that continues throughout infancy and into adolescence and adult life. In this phase, a tension arises between wanting to explore the environment beyond the primary caregiver, yet wanting to be reassured of the primary caregiver's continuous presence. During this time, infants have a hard time making meaning of the positive and negative interactions they have with their caregivers. This may lead to the creation of a mental scheme for a good and loving caregiver, and a mental scheme for a bad and neglectful caregiver.

By about 24 months, the child is able to integrate the frustrating, angry, and loving memories of interactions with mother

Yuganov Konstantin/Shutterstock.com

The infant builds a sense of self and other through the accumulation of many, many interactions with the caregiver. When these interactions are mostly positive, a child will internalize the representation of a loving caregiver that can be used in times of stress for self-control.

or other primary caregiver into a stable representation of self and other. The internalization of the loving other contributes positively to the child's sense of self-esteem, enabling the child to think, "I am someone who is safe, loved, and valued."

The path toward maturity requires that the person achieve a sense of vitality, stability, and inner cohesiveness that is formulated through interpersonal transactions. Psychopathology or dysfunction arises when a person internalizes rigid, rejecting, or neglectful relational experiences and then uses these internalizations to anticipate or respond to real-life social encounters. Since the internalized relational pattern is familiar and well-learned, the person is reluctant to give it up even if it leads to feelings of isolation, anxiety, or self-loathing. The result is recurring maladaptive interpersonal relations, which are evidenced in contemporary friendship, family, work, and intimate contexts and are typically observed in the therapeutic relationship as well (Levenson, 2010; Messer & Warren, 1995).

Ego Psychology

In Freud's psychoanalytic theory, the ego has a variety of functions including managing the expression of impulses, negotiating between the id and the superego, striving to attain goals embedded in the ego ideal, and assessing reality. Anna Freud took these ideas further in *The Ego and the Mechanisms of Defense* (1936/1946), outlining new ego capacities that emerge from infancy through adolescence. She highlighted the various threats that the id poses to the ego at each stage of development and provided a classification of the defense mechanisms the ego uses to protect itself from unruly and unacceptable impulses. **Ego psychology** has become a study of the development and differentiation of the ego as integrative, adaptive, and goal directed (Blanck & Blanck, 1986; Loevinger, 1976).

Anna Freud gave special attention to the period of adolescence as a time of increased sexual and aggressive energy that is linked to the biological changes of puberty. At this time, children are likely to be overwhelmed by their impulses and the ego is more or less fighting for its life. Anger and aggression become more intense, sometimes to the point of getting out of hand. Previously successful defense mechanisms threaten to fall to pieces as intense sexual impulses emerged. During this period, the ego may employ very rigid defenses in order to deny the instinctual drives. Adolescents may waiver in their behavior from loving to mean, compliant to rebellious, and self-centered to altruistic as the ego tries to assert itself in the midst of conflicting and newly energized impulses.

Peter Blos identified the coping mechanisms that emerge in adolescence as young people find ways of adapting psychologically to the physical transitions of puberty. By the end of adolescence, those ego conflicts present at the beginning of puberty are transformed into more manageable aspects of identity construction and expression.

Not all aspects of the ego's functioning arise out of conflict between id and superego. Heinz Hartmann (1939/1964) thought that the concepts of ego, id, and superego were more accurately viewed as three interrelated components of mental functioning that could expand or contract under the influence of one another. He offered a developmental picture of the ego, describing a shift from early self-love to investment in others, and the eventual achievement of adaptive, reality-based thinking.

Building on Hartmann's work, Edith Jacobson (1964) explained how the self is shaped through identification with others. Adolescents achieve new levels of autonomy through the incorporation of moral codes and ethical values. According to Jacobson, the superego is not always a threat to the ego. It can become a stimulus for new levels of ego development when anxiety or guilt signals a need for a new standard of moral behavior.

Implications for Human Development

Psychoanalytic theory emphasizes the tension between interpersonal demands and internal psychological demands in shaping personality. The ego develops skills for dealing with the realities of the interpersonal world. It also develops skills for satisfying personal needs and for imposing personal standards and aspirations about the way these needs are satisfied. The expectations of others—particularly parents—are internalized and given personal meaning in the formation of the superego, thereby accounting for how a child translates the demands of the interpersonal world into a personal way of functioning.

Psychoanalytic theory was unique in its focus on early experiences of childhood, stages of development, family interactions, and unresolved family conflicts as explanations for ongoing adult behavior. Freud's emphasis on the importance of parenting practices and their implications for development has provided one of the few theoretical frameworks for examining parent–child relationships. Many of the early empirical studies in developmental psychology focused on issues that derived from psychoanalytic theory, such as childrearing and discipline practices, moral development, and childhood aggression. These topics will all be taken up in more detail in subsequent chapters.

The psychoanalytic approach recognizes the importance of motives, emotions, and fantasies that guide behavior. Within this framework, human behavior springs at least as much from emotional needs as from reason. The theory suggests that unconscious motives and wishes explain behaviors that appear irrational, self-destructive, or contradictory. Many domains of mental activity—including fantasies, dreams, primary process thoughts and symbols, and defense mechanisms—influence how individuals make meaning from their experiences. The idea that development involves efforts to find acceptable outlets for strong, often socially unacceptable impulses still guides therapeutic interventions with children, adolescents, and adults.

Another significant contribution is recognition of the role of sexual impulses during childhood. Freud believed that a sexual relationship with a loving partner is important for healthy adult functioning. Sexual impulses have a direct outlet in behavior during adult life. However, Freud argued that children also have needs for sexual stimulation and satisfaction. Today, we are more aware of a child's need for hugging, snuggling, and physical warmth with loving caregivers, but most adults still find it difficult to acknowledge that young children have sexual impulses. Childhood wishes and needs, bottled up in the unconscious, guide behavior indirectly through symbolic expression, dreams, or, in some cases, the symptoms of mental disorders.

Blend Images/Shutterstock.com

Throughout adulthood, childhood fantasies and impulses continue to press for expression. Sometimes this childlike behavior can serve a positive function, promoting playfulness, creativity, and joy. Of course, sometimes these impulses can get you into trouble.

We need only look at a daily newspaper to recognize that the acceptance and expression of sexual impulses continue to be points of conflict in modern society. Controversies over sex education and providing contraception to teens, as well as the prevalence of disordered sexual behaviors and the use of sex for the expression of aggression in rape and sexual abuse illustrate the difficulties that people have in dealing with the expression of their sexual impulses.

Links to the Psychosocial Approach

Both psychoanalytic theory and psychosocial theory are stage theories that address basic, qualitative changes in self-understanding and social orientation. Psychoanalytic theory deals with conflicts that the child experiences in satisfying basic needs and impulses, especially sexual and aggressive impulses, within socially acceptable boundaries. The psychosocial approach expands this view by considering the broad range of social demands and expectations that confront people at each point in development as well as the wide variety of competencies and social resources that individuals have for meeting those demands.

Both the psychosocial approach and psychoanalytic theory describe characteristics and functions of the ego system. However, the psychosocial approach goes beyond childhood and adolescence, suggesting the direction for ego development in early, middle, and later adulthood. The psychosocial approach gives a greater role to the individual in guiding and shaping the direction of development through the use of coping strategies that redefine conflicts and identify new resources.

Psychoanalytic theory suggests that basic issues of personal development are in place by adolescence. The results of this development are then played out for the remainder of adult life in a person's defensive style, fixations, typical sexual behavior and sexual fantasies, and the strategies for sublimating sexual and aggressive impulses. In contrast, the psychosocial approach assumes that development goes on throughout life. The skills resulting from accomplishing new developmental tasks are learned, and new social abilities are achieved. The radius of significant relationships expands, bringing new expectations and new sources of social support. As new conflicts arise, they stimulate new growth, and new ego qualities emerge as a result of successfully coping with each new challenge. For a list of the key concepts of psychoanalytic theory, see Table 2.2.

CASE ANALYSIS Using What You Know

1. Analyze the role of the id, the ego, and the superego in Jack Manasky's behavior; in Marilyn's behavior.
2. What evidence is there in the case that unconscious drives are motivating the behavior of Jack and Marilyn?
3. What drives does Jack Manasky satisfy by writing letters to his deceased wife?
4. How might the relationship between Jack and Marilyn be explained through the lens of object relations theory?

Cognitive Developmental Theories

OBJECTIVE 2c Explain the basic concepts of cognitive developmental theories and examine their implications for the study of human development.

Cognition is the process of organizing and making meaning of experience. In psychoanalytic theory, this function was assigned to the ego. Interpreting a statement, solving a problem, synthesizing information, critically analyzing a complex task—all of these are cognitive activities. Cognitive developmental theory focuses specifically on how knowing emerges and is transformed into logical, systematic capacities for reasoning and problem solving. Perhaps the most widely known and influential of the modern cognitive theorists is Jean Piaget (Beins, 2012). His concepts provide the initial focus of this section. Recent interest in the social framework within which cognition develops has been stimulated by the work of L. S. Vygotsky. Several of his important contributions, introduced toward the end of this section, complement and expand the developmental perspective on how cognition emerges and changes over the life course (Lourenço, 2012).

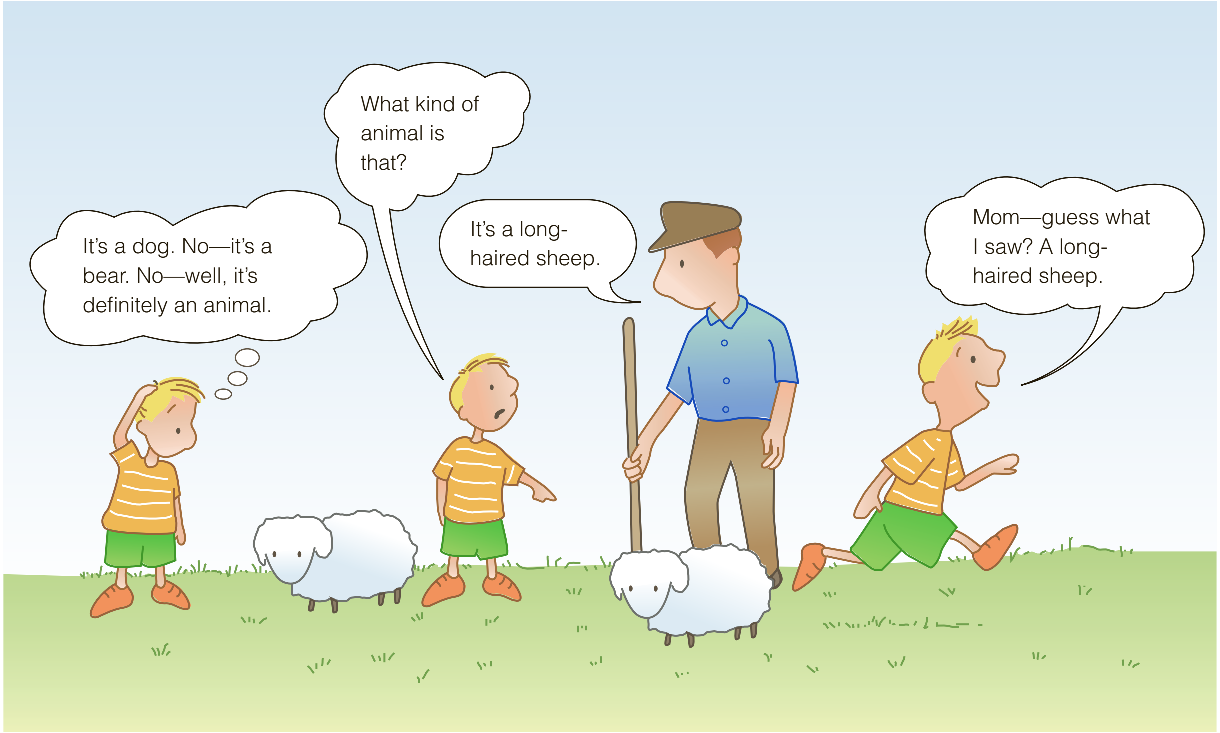
Basic Concepts in Piaget's Theory

According to Piaget, every organism strives to achieve equilibrium. **Equilibrium** is a balance of organized structures, whether motor, sensory, or cognitive. When structures are in equilibrium, they provide effective ways of interacting with the environment. Whenever changes in the organism or in the environment require a revision of the basic structures, they are thrown into **disequilibrium** (Piaget, 1978/1985). Piaget focused on how equilibrium is achieved with the environment through the formation of **schemes** (the structure or organization of action in thought) and **operations** (the mental manipulation of schemes and concepts) that form systematic, logical structures for comprehending and analyzing experience, and on how equilibrium is achieved within the schemes and operations themselves.

Equilibrium is achieved through adaptation—a process of gradually modifying existing schemes and operations in order to take into account changes or discrepancies between what is known and what is being experienced. Adaptation is a two-part process in which the continuity of existing schemes and the possibility of altering schemes interact. One part of adaptation is **assimilation**—the tendency to interpret new experiences in terms of an existing scheme. Assimilation contributes to the continuity of knowing. The second part of adaptation is **accommodation**—the tendency to modify familiar schemes in order to account for new dimensions of the object or event that are revealed through experience. Assimilation operates to preserve existing structures by incorporating new information and confirming that what is already known is useful in making sense of new experiences. Accommodation operates to alter existing structures in light of new information, thereby creating the basis for future assimilation (van Geert, 1998).

Stages of Development

Piaget hypothesized that cognitive development occurs in four stages, each of which is characterized by a unique capacity for organizing and interpreting information. At each new stage, competencies of the earlier stages are not lost but are



It's a dog. No—it's a bear. No—well, it's definitely an animal.
What kind of animal is that?
It's a long-haired sheep.
Mom—guess what I saw? A long-haired sheep.

This infant is exploring and experimenting with the properties of the fruit basket. Visual, tactile and motor senses are all in use as the basket becomes a new hat. What are some examples of sensorimotor exploration that you continue to use?

integrated into a qualitatively new approach to thinking and knowing. The essential features of these stages are introduced here. They will be discussed in greater detail in subsequent chapters. Piaget's theory describes the path in the development of cognition from direct action on objects in infancy to mental actions (operations) and the relationships among mental operations in adolescence.

The first stage, **sensorimotor intelligence**, begins at birth and lasts until approximately 18 months of age. This stage is characterized by the formation of increasingly complex sensory and motor schemes that allow infants to organize and exercise some control over their environment.

The second stage, **preoperational thought**, begins when the child learns a language and ends at about age 5 or 6. During this stage, children develop the tools for representing schemes symbolically through language, imitation, imagery, symbolic play, and symbolic drawing. Their knowledge is still very much tied to their own perceptions.

The third stage, **concrete operational thought**, begins at about age 6 or 7 and ends in early adolescence, around age 11 or 12. During this stage, children begin to appreciate the logical necessity of certain causal relationships. They can manipulate categories, classification systems, and hierarchies in groups. They are more successful at solving problems that are clearly tied to physical reality than at generating hypotheses about purely philosophical or abstract concepts.

The final stage of cognitive development, **formal operational thought**, begins in adolescence and persists through adulthood. This level of thinking permits a person to conceptualize about many simultaneously interacting variables. It allows for the creation of a system of laws or rules that can be used for problem solving. Formal operational thought reflects the quality of intelligence on which science and philosophy are built.

Implications of Piaget's Theory for Human Development

Piaget's theory has had an enormous influence on our understanding of cognition and the way we think about the reasoning capacities of infants and young children. Six implications of the theory for the study of child development are discussed here. First, the theory suggests that cognition has its base in the biological capacities of the human infant—that knowledge is derived from action. For example, infants learn about the features of objects by grasping and sucking on them. Knowledge is constructed rather than passively absorbed. Children as well as adults select, explore, and experiment with objects and later with ideas. They create their knowledge through this active engagement.

As the knower changes, so does what is known. For example, an infant may know a ball through its touch, how it feels in the hand or mouth, through its appearance, and through its response to the infant's actions. A toddler may become aware of the functions of a ball by kicking, throwing, rolling, and bouncing it. At later ages, children understand more about the physical properties of a ball and can link it to other shapes and categories of objects. With each more advanced level of motor, symbolic, and interpersonal capacity, the knower creates a new meaning of objects, people, and the interactions among them. Because of natural interest and through exposure to a wide range of materials, stimuli, and experiences, infants and young children "teach themselves" a great deal of what they know. This perspective has been integrated into instructional strategies in which children are encouraged to construct meaning through direct experience. Through free exploration, which typically requires the coordination of perspectives and the manipulation of interconnected elements, an understanding of the integration of coordinated factors is naturally acquired (Kamii et al., 2001; Kamii, Rummelsburg, & Kari, 2005).

Second, discrepancies between existing schemes and contemporary experiences promote cognitive development. Encounters with all types of novelty—especially experiences that are moderately distinct rather than widely different from what is already known—are important for advancing new ideas and new ways of organizing thought. Extending this idea, encounters with differences in opinion through discussion and reading are just as important in adolescence and adulthood as encounters with different types of sensory materials in infancy and toddlerhood.

Third, infants have the capacity for thinking and problem solving. Although infants do not make use of symbolic strategies, they are able to establish certain logical connections between means and ends that guide their problem-solving efforts.

Fourth, infants, toddlers, and school-age children think in different ways, and the ways they think are different from the ways adults think. This does not mean that their thinking is unorganized or illogical, but the same principles of logic that typically govern adult thought do not govern the thinking of young children.

Fifth, beginning with the period of concrete operations, children can approach problems using many of the principles that are fundamental to scientific reasoning. They can also begin to reason about their reasoning—introducing the importance of **metacognition**, the many strategies used to guide the way we organize and prepare ourselves to think more clearly and effectively.

Sixth, thinking about the social world is regulated by many of the same principles as thinking about objects in the physical world. As we learn about the principles that govern objects and physical relationships, we are also learning about ourselves and others.

Vygotsky's Concepts of Cognitive Development

Although Piaget acknowledged the significance of social factors, especially parents and peers, in the cognitive process, his theory focused on what he believed to be universal processes and stages in the maturation of cognition from infancy through adolescence. In contrast, Vygotsky, often referred to as an interactionist, argued that development can be understood only within a social-historical framework. At the heart of his work is a focus on thinking, especially in childhood, which he links to the development of language and speech.

> The development of the child's thinking depends on his mastery of the social means of thinking, that is, on mastery of speech. . . . This thesis stems from our *comparison* of the development of inner speech and verbal thinking in man with the development of speech and intellect as it occurs in the animal world and the earliest stages of childhood. This comparison demonstrates that the former does not represent a simple continuation of the latter. The very type of development changes. It changes from a biological form of development to a socio-historical form of development. (Vygotsky, 1987, p. 120)

Lower and Higher Mental Processes

Vygotsky was trying to account for the development of higher mental processes from their simpler forms. He saw development as following a continuous path from other animals to humans, and also a discontinuous path. This was captured in his view of *natural* or **lower mental processes**, which could be observed in animal behavior and in the problem-solving behaviors of infants and very young children, and higher mental processes, which arise as children encounter and master the cultural tools of their society. He viewed human beings across cultures as similar to the extent that they shared basic physical characteristics and natural psychological processes, and different depending upon the cultural symbol systems to which they are exposed.

Higher mental processes, particularly language and meaning, emerge from the child's ongoing interactions within social, historical, and cultural contexts, as well as from the child's biological maturation. The child and the culture are intricately interwoven through the process of social interaction. New levels of understanding begin at an interpersonal level as two individuals, initially an infant and an adult, coordinate their interactions. Eventually interpersonal collaboration becomes internalized to shape a child's thinking. Through continuous interactions with others, especially adults and older children, children revise and advance their levels of understanding. Over time, the mastery of **cultural tools,** including symbol systems, permits individuals to alter their environments and guide, regulate, and redefine themselves.

Four key concepts in Vygotsky's theory are introduced here: (1) culture as a mediator of cognitive structuring, (2) movement from the intermental to the intramental, (3) inner speech, and (4) the zone of proximal development.

Culture as a Mediator of Cognitive Structuring

Vygotsky argued that cognitive development can be understood only in the context of culture. Of the many elements of culture that shape cognition, one that was of special interest to Vygotsky was the idea of tools as human inventions that shape thought. *Technical tools*, such as plows, cars, weapons, and computers, and *psychological tools*, such as symbolic systems, counting systems, and strategies for remembering, modify a person's relationship to the environment. Through the use of tools, humans change the way they organize and think about the world. For example, having a cell phone frees people from thinking that they have to be in a specific location, like their home or office, in order to talk with someone. Cell phones change the way people think about the manner and location of interpersonal communications. Vygotsky viewed tools as a means through which the human mind is shaped and modified over the course of history.

Movement from Intermental to Intramental

Perhaps contrary to common sense, Vygotsky argued that high-level mental functions begin in external activity that is gradually reconstructed and internalized. He gave the example of *pointing*. Vygotsky claimed that initially an infant will reach toward an object that is out of reach, stretching the hand in the direction of the object and making grasping motions with the fingers. This is a movement directed to the object. As soon as the caregiver recognizes that the child wants the object and is able to satisfy the child's request, the child begins to modify the reaching and grasping motion into a socially meaningful gesture—pointing. The caregiver's understanding of the gesture and the **intermental** coordination between caregiver and infant result in an **intramental** process for the infant—an understanding of the special relationship between the desired goal, the caregiver as mediator, and pointing as a meaningful sign.

Vygotsky's theory emphasizes the social context of cognitive development. Why might an older sibling be effective for promoting learning in the zone of proximal development?

Inner Speech

Vygotsky (1978) argued that speech plays a central role in self-regulation, self-directed goal attainment, and practical problem solving. He described the problem-solving behaviors of toddlers as involving both speech and action. Toddlers use what was described by Piaget (1952) as **egocentric speech** to accompany their behavior. They talk out loud but do not seem to be concerned about whether anyone can hear them or understand them. He described the talk as egocentric because it did not seem to have any social intention. Piaget suggested that the development of communication began with inner thinking of a very private nonsocialized nature. In toddlerhood, he viewed egocentric speech as evidence of the relative absence of social life and the great extent of nonsocialized thoughts that the child is unable to express.

Vygotsky (1987) proposed a completely different developmental pathway to account for egocentric speech and its function. He viewed speech as beginning in the social interactions between children and adults or other children. The first and foremost function of speech is social. Egocentric speech is a transformation of this social speech inward. The child uses speech that was initially acquired through interactions with others to guide personal behaviors. It does not have a social intention; rather, it is a tool that helps to guide problem solving. Vygotsky viewed egocentric speech and actions as part of the same problem-solving function. The more difficult the problem, the more speech is necessary for the child to find a solution. He observed, "Children solve practical tasks with the help of their speech, as well as their eyes and hands" (Vygotsky, 1978a, p. 26). Eventually, the egocentric speech of an audible nature dwindles (but does not disappear entirely) and becomes **inner speech**.

The Zone of Proximal Development

Taking the idea of internalization further, Vygotsky offered the concept of the zone of proximal development to explain how learning and development converge. The **zone of proximal development** is "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers" (Vygotsky, 1978b, p. 86).

We have all experienced situations in which we were able to solve a task only with the assistance and advice of someone else. The typical efforts of parents to help a child put together a jigsaw puzzle by suggesting strategies, such as selecting all the straight-edged pieces first to make the border, or sorting the many pieces into those with a similar color, are examples of how learning takes place within the zone. Vygotsky suggested that the level of competence a person can reach when taking advantage of the guidance of others reflects the functions that are in the process of maturation, as contrasted to those that have already matured. Learning within the zone of proximal development sets into motion the reorganization and internalization of existing developmental competencies, which then become synthesized at a new, higher intramental level.

Implications of Vygotsky's Theory for Human Development

Vygotsky's theory suggests that the boundaries between the individual and the environment are much less clear than one might infer from most other theories of human development.

Vygotsky directs attention to the guiding role of social interaction and culture in shaping and orienting cognition, thus bringing the study of cognitive development into much greater harmony with the concepts of psychosocial theory than are seen in Piaget's theory.

Several specific implications of Vygotsky's work can be inferred (Davydov, 1995; R. Miller, 2011). First, in contrast to Piaget, who viewed the emergence of logical thought as largely a universal process, Vygotsky considered the nature of reasoning and problem solving as culturally created. Because of the way in which intermental experiences and networks structure intramental events, one's family and others who influence and control the child's early learning and problem-solving experiences will have a strong influence on the structure of one's thinking.

Second, Vygotsky highlighted the role of language as a cultural tool that links each new generation of children with the history and cultural meaning of their ancestors. Language, especially the spoken word, is a bridge between the interpersonal environment and the child's private thoughts.

Third, the concept of a zone of proximal development links development and learning. It assumes a critical role for adults in the child's environment who can identify where a child is with regard to any particular skill area and can then introduce questions, suggestions, tasks, and strategies to help move them to a new level of competence. Vygotsky believed in the interconnection of the learning and teaching processes, arguing that children could never discover everything in a culture's knowledge base just through exploration and experimentation. They need the guidance of more skillful peers and adults.

Finally, individuals can promote their own cognitive development by seeking interactions with others who can help draw them to higher levels of functioning within their zone of proximal development.

Links to the Psychosocial Approach

Piaget's cognitive developmental theory and the psychosocial approach focus on development as a product of discrepancies, referred to as *disequilibrium* in cognitive developmental theory and as *psychosocial crises* in psychosocial theory. Piaget's theory, like the psychosocial approach, proposes a set of stages of development, with each stage growing from and integrating the achievements of earlier stages. Piaget's theory did not offer any hypotheses about the qualitative changes that might follow the period of formal operational reasoning, whereas the psychosocial approach makes clear predictions about the direction of ego development in early, middle, and later adulthood.

Piaget focused on the cognitive domain—especially on the process of knowledge acquisition and logical reasoning. The meaning a person makes of a situation depends largely on the stage of mental development attained. Feelings, social relationships, and self-understanding are viewed as cognitive schemes that are constructed with the same logic that the person applies to the understanding of objects. In the psychosocial approach, cognitive development is referred to as ego development—an understanding of how the self emerges and shapes a personal identity with goals, values, beliefs, and strategies for achieving goals within the constraints of the society. Ego development involves planning, making decisions, coping with challenges, and facing the future with a sense of purpose.

Vygotsky's theory provides an important link from Piaget's emphasis on the maturation of logical reasoning to the emphasis of the psychosocial approach on the maturation of self in society by emphasizing the interpersonal nature of cognition. The idea of a zone of proximal development relates closely to the idea of an expanding network of social relationships, capturing the unique interpersonal and cultural context of all aspects of knowing, whether it is knowing about the logic of the physical world or about the logic of relationships. Vygotsky's theory shares with the psychosocial approach a strong emphasis on the role of culture in guiding social and cognitive development. The two theories view development as an ongoing interaction of the person and the cultural context. One might think of Vygotsky's notion of movement from the intermental to the intramental as a forerunner of the psychosocial concept of identity—a gradual internalization and integration of the roles and social expectations of others into a meaningful sense of one's role in society. For a list of the key concepts of cognitive developmental theory, see Table 2.3.

CASE ANALYSIS Using What You Know

1. How is Jack Manasky using his formal operational reasoning to explain his new symptoms of headaches?
2. How might Marilyn use the concepts of assimilation and accommodation to influence Jack's thinking about trying a new kind of coffee?
3. Think about Jack's letters to his wife. How are the concepts of cultural tools and inner speech related to these letters?
4. Given their interactions, would you say that Jack and Marilyn are products of the same culture? How might changes in culture over time alter cognitive reasoning?

Theories of Learning

OBJECTIVE 2d Explain the basic concepts of learning theories and examine their implications for the study of human development.

Human abilities are diverse, flexible, and can be coordinated or integrated to achieve many different goals. An understanding of the processes of learning and teaching requires concepts that are not linked to specific goals but can be applied broadly across many problem areas (Premack, 2010). For example, observational learning is a common mode through which humans can learn a vast array of behaviors, such as eating with a fork, swinging a bat, speaking in a polite tone of voice, or sharing toys with friends. Learning theorists have proposed mechanisms to account for the relatively permanent changes in behavior that occur as a result of experience. Underlying human beings' extensive capacity to adapt to changes in their environments is their flexible ability to learn. Two theories of learning that have made significant contributions to the study of human development are social learning and cognitive behaviorism.

JGI/Jamie Grill/Blend Images/Getty Images

Social learning theory emphasizes the role of observation and imitation as means of learning new behaviors. Can you think of a new response that you recently learned through imitation?

Social Learning Theory

The concept of **social learning** evolved from the awareness that much learning takes place as a result of **observation** and **imitation** of other people's behavior (Bandura & Walters, 1963). Changes in behavior can occur without being linked to a specific pattern of positive or negative reinforcement. They can also occur without numerous opportunities for trial-and-error practice. A person can watch someone perform a task or say a new expression and imitate that behavior accurately on the first try. The person being observed is called the **model**; the process is called **modeling**.

Early research in social learning theory was devoted to identifying conditions that determine whether a child will imitate a model (Bandura, 1971/2006, 1977, 1986). Children have been found to imitate aggressive, altruistic, helping, and stingy models. They are most likely to imitate models who appear to be powerful and prestigious, in other words, models who control resources or who are themselves rewarded. Bandura and Walters (1963) suggested that children not only observe the behaviors carried out by a model, but they also watch what happens to the model. When the model's behavior is rewarded, the behavior is more likely to be imitated; when the model's behavior is punished, the behavior is more likely to be avoided. This process is called **vicarious reinforcement**. When naughty behaviors go unpunished, they too are likely to be imitated. Through observational learning, a child can learn a behavior and also acquire the motivation to perform that behavior or to resist performing that behavior depending on what is learned about the consequences linked to that behavior. Thus, observational learning can hold the key to self-regulation and to the internalization of standards for resisting certain behaviors as well as for enacting behaviors (Grusec, 1992).

Bandura (1977) pointed out the distinction between learning and performance. A learner might understand features of a task or demands in a situation that are not evident in the learner's behavior. Social learning theory assumes that a great deal of learning goes on through observation, but that much of it is not observed in behavior unless the reinforcement conditions are conducive.

Social learning theory has taken an increasingly cognitive orientation, sometimes referred to as social cognitive theory (Bandura, 1989, 1991, 2001, 2012). Through observational learning, the child becomes acquainted with the general nature of the situation as well as with the specific behaviors. Direct reinforcement or non-reinforcement provides information about how to behave in a certain situation. Moreover, people watch others, learn about the consequences of their actions, and remember what others have told or shown them and what they have read or learned about the situation. Over time, one forms a symbolic representation for the situation, the required behaviors, and the expected outcomes. A worker may learn that with one type of supervisor, it is appropriate to ask lots of questions and offer suggestions for ways of solving problems, whereas with another supervisor, it is better to remain quiet and try not to be noticed. The rules for behavior in each setting are abstracted from what has been observed in watching others, what happened following one's own behavior in the past, and what one understands about the demands in the immediate situation. Through social learning, individuals develop an understanding of the social consequences of behavior, leading to new patterns of behavioral expression and self-regulation. The culmination of this learning process is what Bandura (2001, 2008) referred to as **efficacy**, including planning intentional actions, guiding and directing one's own behaviors toward a goal, and reflecting on one's actions to assess their quality, impact, and purpose.

Implications of Social Learning Theory for Human Development

The principles of social learning theory are assumed to operate in the same way throughout life. The concept of social learning highlights the relevance of models' behavior in guiding the behavior of others. These models may be parents, older siblings, peers, entertainment stars, or sports heroes. Because new models may be encountered at any life stage, new learning through the process of observational learning is always possible. Exposure to a certain array of models and a certain pattern of rewards or punishments results in the encouragement to imitate some behaviors and to inhibit the performance of others. The similarity in behavior among people of the same age reflects their exposure to a common history of models, rewards, and punishments. Recognition of the potential impact one has as a model for others—especially in the role of parent, teacher, clinician, counselor, or supervisor—ought to impart a certain level of self-conscious monitoring about the behaviors one exhibits and the strategies one employs in the presence of those who are likely to perceive one as a model for new learning.

Cognitive Behaviorism

Cognitive behaviorism is the study of the many thoughts, ideas, and memories that influence behavior. In addition, it is a study of the ways people represent behavior in thought. For example, athletes think about their performance and visualize the actions needed to perform well. This is a cognitive representation of actions. Edward Tolman (1932/1967, 1948) introduced the notion of a **cognitive map**—a mental representation of the learning environment. According to Tolman, individuals who perform a specific task in a certain environment attend primarily to that task, but they also form a representation of the setting. The cognitive map includes expectations about the reward system, existing spatial relationships, and the behaviors that are most highly valued in that setting.

An individual's performance in a situation represents only part of what has been learned in the setting. Imagine that you are going to your local grocery store to buy some milk and eggs. You know exactly where they are located in the store. If another shopper asks you where the coffee is, you can tell them the location since you have been in that store many times. You have a cognitive map of the store that is more extensive than the path you will take to get the milk and eggs.

According to Walter Mischel (1973, 1979; Mischel & Shoda, 1995), six types of cognitive and emotional factors influence a person's behavior in a situation and account for continuity in how people respond across situations: encodings, expectancies and beliefs, affects (feelings and emotional responses), goals and values, competencies, and self-regulatory plans (see FIGURE 2.2 ▶). **Encodings** refer to constructs or schemes the person has about the self, the situation, and others in the situation. **Expectancies** refer to cognitive assessments about one's ability to perform, ideas about the consequences of one's behavior, and the meaning of events in one's environment.

Affects are the feelings and emotional reactions or physiological responses that are associated with a situation. Feelings of anger, fear, arousal, excitement, or jealousy might interact with expectancies and encodings to guide behavior. **Goals** and **values** are related to the relative importance one places on the outcomes of situations. One person may value high levels of task performance, whereas another may value success in social situations. One's behavior in a situation is influenced by how one values its possible outcomes. **Cognitive competencies** consist of knowledge, skills, and abilities.

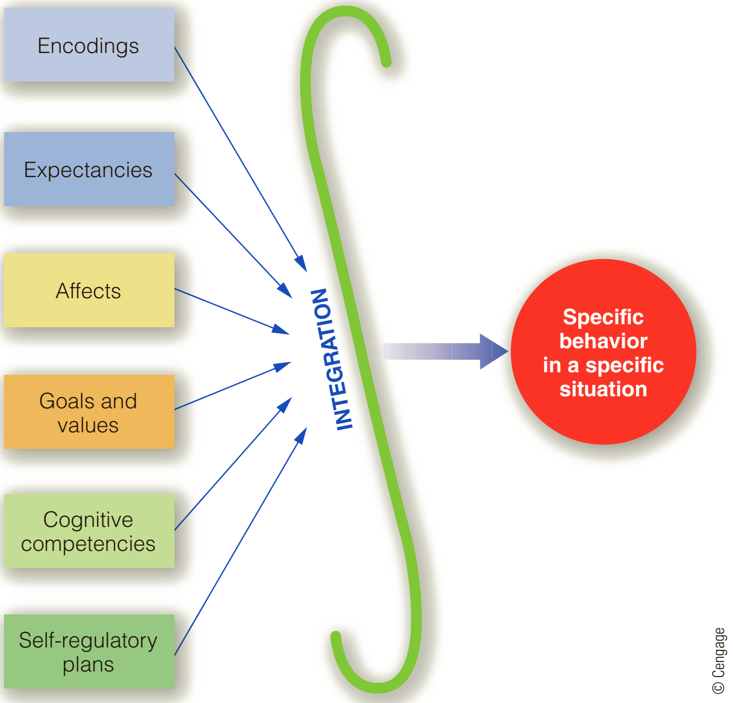

FIGURE 2.2 ▶ SIX COGNITIVE AND AFFECTIVE DIMENSIONS THAT INFLUENCE BEHAVIOR

APPLYING THEORY AND RESEARCH TO LIFE

Cognitive Behavioral Therapy

Building on the traditions of cognitive developmental theory, cognitive behaviorism, and attribution theory, cognitive behavioral therapy (CBT) is a general term that applies to a variety of therapies that share certain similarities. A premise of cognitive behavioral therapy is that our thoughts cause our feelings or reactions to events, not the events themselves. This is important because we can alter the way we think about events much more readily than we can alter the events themselves (Clark, Holifield, Leahy, & Beck, 2009). Since people differ in the way they categorize and evaluate a stimulus, the same situation might create feelings of discouragement and depression in some people and feelings of determination in others. For example, one person might react to a bad grade on a test as evidence that she is not smart enough to do well; another person might react to the same grade as evidence that she needs to study harder.

Aaron Beck (1976/1979), the founder of cognitive therapy, began his work in the treatment of depression. He found that patients suffering from depression spoke consistently of themes of loss, incompetence, and failure. They viewed themselves as failures; they perceived their efforts to alter their situation as useless, and their expectancies of the future as bleak. Beck began to focus his therapeutic effort on guiding patients to examine their emotional reactions and learn new ways of reacting.

CBT is based on the scientifically supported assumption that most emotional and behavioral reactions are learned. Therefore, the goal of CBT is to teach clients ways of unlearning their problematic reactions and to learn a new way of reacting by examining their thoughts in light of new information or alternative interpretations (National Association of Cognitive Behavioral Therapists, 2014). The therapy takes an inductive approach, encouraging clients to consider their thoughts as hypotheses that can be questioned or tested and then changed in order to be more appropriately adapted to reality. The therapist focuses on teaching the client rational, self-counseling skills that can be practiced through weekly homework and applied to daily situations outside of the therapy session. The therapy also teaches clients to examine their problems with a degree of calm detachment. If a person is upset about a problem, then the person actually has two problems, the troubling situation and the distress associated with their reaction to it. Finding ways to reduce the distress allows the person to examine the problem using higher order cognitive skills rather than affect-driven stress reduction responses.

Cognitive behavioral therapy has been shown to be effective in the treatment of depression, panic disorder, bulimia (an eating disorder), and post-traumatic stress disorder (Baker, McFall, & Shoham, 2009; Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012). A number of clinical studies have shown that cognitive behavioral therapy is more long lasting as a treatment for these disorders than treatment using medication. In other words, once the treatment has ended, patients who have had cognitive behavioral therapy are substantially less likely to relapse than those who were treated with medication. The implication is that for these conditions, a therapeutic process can result in a relatively permanent change in thought, affect, and specific behaviors designed to help the client achieve goals.

Critical Thinking Questions

1. What are the links between the six elements of cognitive behaviorism (Figure 2.2) and cognitive behavioral therapy?
2. Based on what you know about psychoanalytic theory and cognitive behaviorism, what might be some similarities and differences in the therapeutic approaches of these two theories?
3. What are some ways in which cognitive behavioral therapy builds on Piaget's cognitive developmental theory? How might the therapy be viewed in terms of Vygotsky's idea of the zone of proximal development?
4. What are some limitations to cognitive behavioral therapy? What are some features of the client or the problem that would not lend themselves well to cognitive behavioral therapy?

Self-regulatory plans are strategies for achieving one's goals, including techniques for managing internal emotional states, creating a plan, and putting the plan into action (Kross, Mischel, & Shoda, 2010; Mischel, 2012). Self-regulation is especially important in situations where temptations, frustrations, or self-doubt threaten to pull one away from important goals (Mischel & Ayduk, 2002). As people become increasingly aware of the effects of stimuli on their behavior, they can learn to overcome, channel, or eliminate those influences that tempt them to abandon their goals. The box, **Applying Theory and Research to Life box** Cognitive Behavioral Therapy, illustrates how the principles of cognitive behaviorism have been incorporated into a therapeutic approach to help clients alter unwanted or distressing thoughts, affect, and behavior.

Implications of Cognitive Behaviorism for Human Development

Cognitive behaviorism suggests that the learner acquires an outlook on the learning situation that influences subsequent learning and performance. This outlook influences the learner's feeling of familiarity with the task, motivation to undertake the task, optimism about performing the task successfully, and strategies for approaching the task. In addition to everything a parent, teacher, or supervisor might do to structure a learning environment, one must always take into account the outlook that the learner brings to the task. Differences in expectancies, self-control strategies, values, emotional reactions, and goals all influence the way individuals approach a learning situation and the behaviors they are likely to exhibit in the situation.

In order to understand why people behave as they do in a specific situation, one needs to understand the meaning they give to the situation. Although information or skills can be learned, they will not be expressed in action unless expectations about the self and the environment justify their enactment.

Links to the Psychosocial Approach

The psychosocial approach assumes that growth and change continue throughout the life span; however, it does not account for the exact processes by which new behaviors, new coping strategies, or new ego strengths are acquired. The learning theories provide explanations for the ways in which the patterns of daily events shape the direction of adaptation and growth. They offer insight into the processes through which society's rules, norms, and customs become internalized and translated into habits, preferences, and expectations, which become generalized across common situations. The learning theories emphasize the significance of the immediate environment in directing the course of growth. They help to explain why habits or patterns of behavior may be difficult to change, even when they appear to be dysfunctional. The key terms introduced by social learning theory and cognitive behaviorism are listed in Table 2.4.

CASE ANALYSIS Using What You Know

1. Using the concepts in Figure 2.2, develop an approach that Marilyn might use to modify her father's coffee-drinking behavior.
2. Speculate about how the two different settings—Jack's living room and the coffee shop—might influence Jack's behavior. What might be some differences and some consistencies in his behavior in these two settings?
3. Explain how concepts from social learning theory, including modeling, imitation, and vicarious reinforcement, might apply to the development of behavioral habits, like drinking coffee or smoking cigarettes.

Table 2.4 Basic Concepts of Social Learning Theory and Cognitive Behaviorism

Social Learning	Cognitive Behaviorism
Observation	Cognitive map
Imitation	Encodings
Model	Expectancies
Modeling	Affects
Vicarious reinforcement	Goals
Social learning	Values
Efficacy	Cognitive competencies Self-regulatory plans

Cultural Theory

OBJECTIVE 2e Explain the basic concepts of cultural theory and examine its implications for the study of human development.

The concept of **culture**, although defined in a variety of ways by anthropologists, political scientists, sociologists, and psychologists, refers here to the learned systems of meanings and patterns of behaviors that are shared by a group of people and transmitted from one generation to the next. **Physical culture** encompasses the objects, technologies, structures, tools, and other artifacts of a culture. **Social culture** consists of norms, roles, beliefs, values, rites, and customs (Betancourt & Lopez, 1993; Herkovits, 1948; Rohner, 1984; Triandis, 1994; Triandis et al., 1980).

Culture has been described as a **worldview**—a way of making meaning of the relationships, situations, and objects encountered in daily life. Basic ideas, such as whether people are considered to be in control of nature or a part of nature, who is included in the definition of family, what characteristics are considered signs of mental health or mental illness, which acts are construed as hostile or nurturing, which aspects of the environment are considered dangerous or safe—all these and many other mental constructions are shaped by culture (Kagitcibasi, 1990). Culture guides development, not only through encounters with certain objects, roles, and settings, but also through the meanings linked to actions.

Weisner and Lowe (2004) clarify this process using the term **cultural pathways**. According to this view, adults in each culture have values and goals for themselves and for their children that shape and organize the socialization process and activities of daily life. They state, "Activities are made up of values and goals; resources needed to make the activity happen; people in relationships; the tasks the activity is there to accomplish; emotions and feelings of those engaged in the activity; and a script defining the appropriate, normative way we expect to do that activity" (Weisner & Lowe, 2004, p. 6).

The idea that engaging in the specific routines and activities of daily life shaped developmental pathways was captured early in the field of cultural anthropology through the work of Ruth Benedict. She introduced the principle of **cultural determinism** (Benedict, 1934/1950), which suggests that the individual's psychological experiences are shaped by the expectations, resources, and challenges posed by one's specific cultural group. Cultural determinism suggests that an individual's development is shaped through **enculturation**. **Culture carriers**, such as parents, teachers, religious leaders, and elders, use strategies to transmit critical practices and values. For example, in Japanese culture, infants and their mothers are expected to establish a sense of closeness and interdependence. This is achieved by keeping the infant physically close to the mother. Mothers and infants practice co-sleeping, co-bathing, and very few experiences of physical separation.

In European American culture in the United States, by contrast, mothers are expected to foster autonomy in their infants. This is achieved by encouraging exploration, choice, and early experiences of physical separation from the mother for sleeping and play. The two cultures have different worldviews and different values about interpersonal and family relationships. These values are transmitted through their childrearing practices (Bornstein, Cote, Haynes, Suwalsky, & Bakeman, 2012). Two theoretical dimensions that allow one to compare cultures are presented here: cultural continuity and discontinuity, and individualism and collectivism.

Cultural Continuity and Discontinuity

The extent to which development is viewed as distinct stages of life depends on the degree to which socialization within a culture is characterized by continuity or discontinuity. Cultural **continuity** is found when a child is given information and responsibilities that apply directly to that child's future adult behavior. For example, Margaret Mead (1928/1950) observed that in Samoan society, girls of 6 or 7 years of age commonly took care of their younger siblings. As they grew older, their involvement in the caregiving role increased; however, the behaviors that were expected of them were not substantially changed. When there is continuity, development is a gradual, fluid transformation, in which adult competencies are built directly on childhood accomplishments.

Jupiterimages

Dressed in her ball gown and wearing the traditional tiara, Lucinda dances with her father at her Quinceañera. This cultural celebration is a rite of passage at the 15th birthday, marking a girl's transition into womanhood.

Cultural **discontinuity** is found when a child is either barred from activities that are open only to adults or is forced to "unlearn" information or behaviors that are accepted in children but considered inappropriate for adults. The change from expectations of virginity before marriage to expectations of sexual responsiveness after marriage is an example of discontinuity. Cultures that have discrete, age-graded expectations for people at different periods of life produce a pattern of development in which age groups have distinct characteristics and appear to function at different skill levels. These societies are likely to be marked by public ceremonies, graduations, and other **rites of passage** from one stage to the next.

Individualism and Collectivism

The dimensions of individualism and collectivism provide another lens for comparing cultures (Triandis, 1990, 1995, 1998). **Individualism** refers to a worldview in which social behavior is guided largely by personal goals, ambitions, and pleasures, which may or may not coincide with the interests of the group. Independence and personal achievement are valued. When conflicts arise between group and personal goals, it is considered acceptable and perhaps expected that personal goals will come first.

Collectivism refers to a worldview in which social behavior is guided largely by goals that are shared by a collective, such as a family, tribe, work group, or political or religious association. Interdependence and group solidarity are valued. The in-group creates norms, goals, and beliefs that are enculturated and endorsed by its members. When conflicts arise between group goals and personal goals, a person is expected to act in the best interest of the group.

People from different cultures process social information somewhat differently, influenced in part by the collectivist or individualistic orientation of the culture. For example, both native Chinese and Western adults process information about characteristics of the self in the same area of the prefrontal cortex. However, Chinese adults also process information about characteristics of their mothers in this same area of the brain, an area that in Western adults is involved only in thinking about the self. The implication is that for Chinese adults, a strong cultural tie between self and others is supported by a neural pathway for thinking about self and significant others (Ambady & Bharucha, 2009; Zhu, Zhang, Fan, & Han, 2007).

Across cultures, people have to achieve some of the same basic developmental tasks, but the degree to which the culture is collectivistic or individualistic will influence what the people in a culture think is the ideal state and what is necessary to achieve that state. All cultures have some expectations for the formation of social relationships and social bonds, but the pathways that are emphasized as high quality or most desirable are different. In an individualistic developmental pathway, social obligations are constructed through agreements among the individual participants in the relationship. Opportunities to decide with whom you want

HUMAN DEVELOPMENT AND DIVERSITY

Implications of Individualism and Collectivism for Parenting Practices

The constructs of individualism and collectivism refer to two different value systems that characterize a culture. Individualism encourages and celebrates individual accomplishments and self-expression; collectivism encourages and celebrates interdependence and the strength of the community. Every society requires some blend or balance between these two perspectives. In order to survive, a group must be able to support both the *I* and the *We*, the individual person and the group. However, as one interacts with people from different cultural backgrounds, it is helpful to be aware of the dominant orientation toward either individualism or collectivism in order to achieve greater insight into the person's likely motivations, goals, and sense of moral obligation (Greenfield, Trumbull, & Rothstein-Fisch, 2003). Table 2.5 summarizes the features of these two orientations.

These contrasting values have implications for the behaviors that parents value and the ways athey interact with their children. Individualist cultures encourage more independent play. They foster a child's autonomy and self-expression by allowing greater physical distance between the child and the caregiver, asking for the child's opinions, and allowing children to have a voice in decision making. Children are praised for doing things on their own and moving toward self-reliance. In both subtle and specific ways, children in individualist cultures are encouraged to compete with each other and to feel pride in their individual achievements.

Children in collectivist cultures are kept closer to their parents or caregivers during infancy. They are more likely to be nurtured through longer periods of breastfeeding, carried or held closely during infancy, and socialized through gentle encouragement and indulgences well into childhood. Families in collectivist cultures usually include extended kinship groups that all play an active role in a child's comfort, socialization, and care. Children are taught to be respectful of their elders and to show deference for adults' opinions and decisions. A strong value for sharing and cooperation leads to encouragement for children to share their belongings and to learn from one another. Children are praised for behaviors that evidence responsibility for others, a sense of duty, and commitment to the family (Bornstein & Lansford, 2010; Greenfield, Suzuki, & Rothstein-Fisch, 2006).

Table 2.5 A Comparison of Individualism and Collectivism

Individualism	Collectivism
Fosters independence	Fosters interdependence
Values individual achievement	Values group success
Promotes self-expression	Promotes adherence to norms
Values individual thinking	Values group consensus
Associated with egalitarian relationships	Associated with hierarchical roles and respect for elders
Associated with private property and individual ownership	Associated with shared property and group ownership

Critical Thinking Questions

1. Joan and Dave get married and have a child. Joan comes from a cultural background that has a collectivist orientation. Dave comes from a cultural background that has an individualist orientation. They are discussing how to discipline their young child.
    a. What kinds of strategies might Joan elect to use?
    b. What kinds of strategies might Dave elect to use?
    c. Under what circumstances might they find themselves in conflict over their approach to childrearing?
    d. What kinds of childrearing approaches might they devise that would be acceptable to both of them?
2. Some researchers take issue with the idea that cultures can be characterized as collectivist or individualist. What are the limitations of these concepts? Are they overly simplistic? Do they reflect real differences in people's attitudes and beliefs? Do they help explain differences in the behaviors of people from various cultural backgrounds? What kinds of evidence would you want to have in order to be confident about using these constructs?
3. Aside from the ideas of individualism and collectivism, what other ideas do you find useful in characterizing cultural orientations that are transmitted from one generation to the next?

to have relationships and how to behave within those relationships are maximized. As a result, there is considerable variability in the nature and quality of interpersonal relationships. In the collectivistic or interdependent developmental pathway, social obligations and responsibilities are more important, and more clearly defined. There is greater consistency in the scripts for specific relationships and greater agreement about the importance of preserving those relationships, even when those obligations require personal sacrifice (Greenfield, Keller, Fuligni, & Maynard, 2003). For example, arranged marriages are more common in collectivistic cultures, whereas marriages based on romantic love and personal choice are more common in individualistic cultures.

Typically, societies marked by greater complexity, affluence, social mobility, and cultural diversity tend to be more individualistic in their worldview (Greenfield, 2009). Factors including greater exposure to education, increased access to technology, and increased globalization tend to move cultures away from the collectivistic and toward the individualistic pathways.

People within cultures can also be described as adhering to more individualist or collectivist values. Thus, not everyone in a collectivist culture equally endorses the collectivist worldview. Subgroups within a society may differ in how much their values reflect the dominant individualist or collectivist orientation of the larger society. The **Human Development and Diversity** box Implications of Individualism and Collectivism for Parenting Practices provides a discussion of the implications of individualism and collectivism for parenting.

Implications for Human Development

Culture and biological development interact to determine how each period of life is experienced. This concept is illustrated by the ways in which different cultures mark an adolescent girl's first menstruation (Mead, 1949/1955). In some societies, people fear menstruation and treat the girl as if she were dangerous to others. In other societies, she is viewed as having powerful magic that will affect her own future and that of the tribe so she is treated with new reverence. In still others, the perceived shamefulness of sex requires that the menstruation be kept as secret as possible. The culture thus determines how a biological change is marked by others and how it is experienced by the person.

Societies vary in the extent to which people are expected to make significant decisions during each life period and in the range of choices that are available. The United States is a highly individualistic culture. American adolescents are expected to make decisions regarding sex, work, politics, religion, marriage, and education. In each of these areas, the alternatives are complex and varied. As a result, adolescence is prolonged, and the risk of leaving this period without having answers is great.

People who migrate to the United States from more collectivistic cultures or who are members of more collectivistic **subcultures** may experience even more stress during this period as their values for family and group allegiances and their scripts for behavior come into conflict with the individualistic orientation of the larger cultural context. In cultures that offer fewer choices and provide a clearer path from childhood to adulthood, adolescence may be brief and relatively free of psychological stress.

Cultures not only differ from one another, but also some societies are more culturally diverse than others. The process of **globalization** includes "the rapid spread of materials and products, ideas, images, capital flows, and people across spaces and borders (national or otherwise) that formerly were far more difficult if not impossible to connect" (Weisner & Lowe, 2004, p. 6). With increased global travel, migration, global communication systems, and opportunities to study or work in other cultures, most contemporary societies are becoming more culturally diverse than in the past. This means that there may be tensions between dominant and minority cultures as well as conflicts among ethnic groups. There are also new opportunities for the emergence of mixed cultural identities. The intermingling of cultural practices and related values could lead to new forms of adaptation and new worldviews (Kagitcibasi, 2007/2009).

Links to the Psychosocial Approach

The psychosocial approach is based on the assumption that culture contributes fundamentally to individual development. Basic cultural values regarding generosity, self-control, independence, or cooperation can be interpreted from infant caregiving practices. Psychosocial theory assumes that individual development is a product of continuous interaction between the developing person and the demands and resources of the cultural environment.

Using the metaphor of cultural pathways, we assume that individuals in all cultures have to address certain developmental tasks, such as the establishment of interpersonal relationships, but the way their pathways are structured, the activities that are included along the path, and the ideals or goals that adults strive to achieve differ across cultures. According to the psychosocial approach, all cultures must be able to adapt to changes in economic, environmental, and intercultural conditions in order to survive. Individual development is interwoven with the ability of the society to adapt and continue. For a list of the key concepts of cultural theory, see Table 2.6.

CASE ANALYSIS Using What You Know

1. From the case of Jack Manasky and Marilyn, deduce the cultural norms for the relationship of an adult daughter and an aging father.
2. Describe a hypothetical cultural context in which Jack and Marilyn might have a very different type of relationship and a different style of interaction.
3. Explain how the cultural value of individualism and independence are expressed in this case.

Social Role Theory

OBJECTIVE 2f Explain the basic concepts of social role theory and examine its implications for the study of human development.

Social role theory traces the process of socialization and personality development through the person's participation in increasingly diverse and complex social roles (Brim, 1966; Parsons & Bales, 1955). A social role is any set of behaviors that has a socially agreed-upon function and an accepted code of norms (Biddle, 1979; Biddle & Thomas, 1966; Brown, 1965).The term *role* was taken from the context of the theater. In a play, actors' behaviors are distinct and predictable because each actor has a part to play and follows a script. You will recall this metaphor from Shakespeare's analysis in *As You Like It*: "All the world's a stage, / and all the men and women merely players. / They have their exits and their entrances, / and one man in his time plays many parts" (Act 2, scene 7).

Role theory applies this same framework to social life (Biddle, 1986). The three elements of concern to role theory are the patterned characteristics of social behavior (**role enactment**); the parts or identities a person assumes (**social roles**); and the scripts or shared expectations for behavior that are linked to each part (**role expectations**). Social roles serve as a bridge between the individual and the society. Every society has a range of roles, and individuals learn about the expectations associated with them. As people enter new roles, they modify their behavior to conform to these role expectations. Each role is usually linked to one or more related or **reciprocal roles**. The student and the teacher, the parent and the child, and the salesperson and the customer are reciprocal roles. Each role is partly defined by the other roles that support it. The function of the role is determined by its relation to the surrounding role groups to which it is allied.

Four dimensions are used to analyze the impact of social roles on development: the *number* of roles a person occupies; the *intensity* of role involvement, or how deeply the person identifies with the role; the amount of *time* the role demands; and the extent to which the expectations associated with each role are either highly *structured* or *flexible* and open to improvisation. These features help account for experiences of role strain and role overload at various periods of life when the demands and intensity of multiple roles converge (see the **Applying Theory and Research to Life** box Role Strain and Parenthood).

Implications for Human Development

All cultures offer new roles that await individuals as they move from one stage of life to another. Some of these roles may be directly associated with age, such as the role of a high school

Frank Siteman/PhotoEdit

ImageBroker/Glow Images

The social role of healer can be found in most cultures. Although the costumes and techniques may differ, healers typically have access to knowledge not shared by most of the people in the society. The role of healer exists in coordination with the reciprocal role of patient or a person seeking a cure. What are some of the role expectations associated with healers in our society?

APPLYING THEORY AND RESEARCH TO LIFE

Role Strain and Parenthood

A recurring theme in the literature on parenthood is the experience of role strain. **Role strain** is defined as a sense of difficulty in meeting perceived role expectations or balancing competing role demands (Biddle, 1986). Each of the following dimensions of social roles may contribute to parental role strain: role intensity, time required, the structure or flexibility of the role, and the number and characteristics of other roles. Because the parent role has great intensity, the sense of involvement in all the behaviors associated with the role intensifies, and so does anxiety about failure to meet the expectations of the role. First-time parents especially may have little confidence in their ability to fulfill their roles, and the level of worry associated with the role rises accordingly.

The parent role takes a lot of time. Most first-time parents underestimate how much time infants and toddlers require. When new parents reflect on the time they spend in a variety of social roles, they point to the parent role as more time consuming than any other role, now or in the past.

Role strain linked with parenting is related to the structure of the role. Some adults have very clear ideas about how they should enact their parent role, but many are unsure. Partners are likely to differ in their views on childrearing techniques. These differences require time to resolve. Because of the hardships or distress they recall from their own childhoods, many adults do not want to raise their children the way they were raised themselves. They have to learn a new script for this role.

When parenting is added to other adult roles, especially those of worker and spouse, the demands of the new parental role may seem overwhelming. Most parents are also enacting a worker role. Workplace conditions that allow demands of the work role to spill over into family life can be a cause of work–family conflict and role strain. With corporate downsizing, many workers find that they have much more to do, more functions to fill, and increased pressure to do work after hours or at home. The need to make a long commute to work, expectations to bring work home, and expectations to be available for telephone or online interactions from home are all examples of work demands that can increase parental role strain (Voydanoff, 2005). Societies differ in the extent to which family responsibilities come into conflict with one's worker role. In more collectivist cultures, it is likely that family commitments place substantial strains on individuals who are also engaged in demanding work settings (Allen, French, Dumani, & Shockley, 2015).

There are at least five ways to minimize role strain associated with the parent role (Allen, 2001; Bornstein, 2012; Cowan & Cowan, 2012; Newman, 2000):

1. Focus on a small number of expectations for the parenting role and focus on finding pleasure in meeting those expectations rather than worrying about the many expectations that are not being met.
2. Delegate role responsibilities can reduce role strain. Parents who can hire others to help with some of the parenting responsibilities or who can turn to family members or friends for help will experience less role strain than those who are solely responsible for the parenting role. Couples who can flexibly alter and share household responsibilities in response to the demands of parenting will experience more satisfaction and less strain.
3. Integrate several aspects of the role in one activity to reduce role strain. Some parents become quite inventive about ways to maintain contact with their infant while carrying out household chores and other work and also preserving time with each other.
4. Role strain is reduced when partners reach consensus about their parent roles. New parents who have resolved their differences regarding childrearing philosophy, child care activities, and the division of household responsibilities experience less role strain and a higher level of marital satisfaction than those who continue to have opposing views on these issues.
5. Either find a work environment that has supportive attitudes and policies regarding work–family coordination, or take steps to change the existing work culture to be more flexible and positive toward workers who are trying to balance concurrent family and work roles and responsibilities.

Critical Thinking Questions

1. Identify the behaviors you would be likely to observe if parents are experiencing role strain. What types of emotional states might you observe?
2. Hypothesize how parental role strain might influence one's relationships with other family members. How might it influence one's performance as a worker?
3. Discuss the factors that might make it difficult for partners to reach consensus about childrearing in order to reduce role strain.
4. Predict how characteristics of the child or children in the family might contribute to parental role strain. What are some of these characteristics?
5. Analyze some demands of the work role that might produce work–family conflict and parental role strain. What are some characteristics of the workplace that might reduce parental role strain?

student. Other roles may be accessible only to those of a certain age who demonstrate other relevant skills, traits, or personal preferences. In many elementary schools, for example, the fifth-grade students become eligible to serve in the role of crossing guard to help the younger children get across the streets near the school. Families, organizations, and the larger community have implicit theories of development that determine what role positions open up for individuals in each age group. Some of the most important life roles persist across several stages, including child, parent, and sibling. The expectations for role performance remain the same in some respects, but change in others. We can begin to see how social roles provide consistency to life experiences and how they prompt new learning.

Involvement in personal relationships and social groups contributes to the formation of one's **social identity**—that aspect of the self-concept that is based on membership in a group or groups and on the importance and emotional salience of that membership (Tajfel, 1981). Some of these role relationships are personal—based on family, friendship, or intimate relationships. Others are political, religious, or ethnic. Some aspects of one's social identity may be associated with a stigmatized group, such as being homeless, unemployed, or poor (Lott, 2012). In modern societies, people are members of many groups and form complex social identities; many roles and their varying meanings and values are balanced and synthesized. Understanding a person's social identity helps account for which groups a person may view as in-groups and out-groups, why a person might discriminate against certain out-groups, or how a person's views of fairness and justice may be shaped (Simon & Klandermans, 2001).

The idea that one's social identity is crafted from experiences in a variety of roles is illustrated in the following discussion about people who undergo the process of naturalization to become U.S. citizens.

> Several people I talked to implicitly compared citizenship status to other social divisions, particularly race. In thinking about changes brought about by naturalization, these respondents emphasized that while they were being formally incorporated into membership, they would remain outsiders because citizenship status is not a visible characteristic. A thirty-year-old Taiwanese immigrant explained his experience of racialization: "Well, sometimes, being American is not something you say about yourself. You have to depend on people's point of view and perspective. How people see me, because I don't look like American. So I would say I am American after I finish the process (*of naturalization*) but still it's so hard to reach people that I am American especially when I am walking along a road and one of the cops stops me and I don't think he looks at me like I am American". . . . Despite demographic realities, whiteness continues to be associated with being a real American. (Aptekar, 2015, p. 80)

This narrative illustrates the complexity of social identity, in this case for people who decide to pursue a path to citizenship in a new country. Their experience of naturalization, and its accompanying status as an American citizen, has to be integrated with other social categories including ethnicity, race, social class, and gender.

Links to the Psychosocial Approach

Role relationships provide a central mechanism through which the socialization process takes place. In the psychosocial approach, one might think of the radius of significant relationships as an interconnected web of reciprocal roles and role relationships through which the expectations and demands of society make themselves known. The idea of reciprocity in roles is closely linked to the concept of interdependence of people at different psychosocial stages. The capacity of adults to cope with the challenges of their life stages and to achieve new ego strengths is intricately linked to the ability of children and youth to flourish and grow. Social role theory helps clarify why this is so important, because children and adults occupy many reciprocal roles.

In the following chapters, we describe a number of life roles especially related to family, school, and work. As the number of roles increases, individuals must learn some of the skills of role-playing, role differentiation, and role integration. The developmental crisis of individual identity versus identity confusion emphasizes the challenge of being able to integrate several diverse roles in order to preserve a sense of personal continuity. With each new role, one's self-definition changes and one's potential for influencing the world increases. For a list of the key concepts of social role theory, see Table 2.7.

CASE ANALYSIS Using What You Know

1. In the case of Jack Manasky and Marilyn, describe how Marilyn may be defining her role as the adult child of a widowed father.
2. Hypothesize factors that may contribute to role strain for adult children who are trying to care for their aging parents. What evidence do you see for this in the case of Jack Manasky and Marilyn?
3. Explain the idea of reciprocal roles. What evidence of reciprocal roles do you see in the case of Jack Manasky and Marilyn? How might the concept of reciprocal roles help explain some of the stresses associated with widowhood?

Systems Theory

OBJECTIVE 2g Explain the basic concepts of systems theory and examine its implications for the study of human development.

A **system**—whether it is a cell, an organ, an individual, a family, or a corporation—is composed of interdependent elements that share some common goals, interrelated functions, boundaries, and an identity. Systems theories attempt to describe and account for the characteristics of systems and the relationships among the component parts found within the system. Systems theories take the position that the whole is more than the sum of its parts. The system cannot be fully understood by identifying each of its component parts. A language system, for example, is more than the capacity to make vocal utterances, use grammar, and acquire vocabulary. It is the coordination of these elements in a useful way in a context of shared meaning.

Characteristics of Open Systems

Individuals, families, communities, schools, and societies are all examples of open systems. Open systems are in ongoing interaction with their environments. These systems have boundaries that help establish their identity: A cell has a cell wall; a team has a roster of members; a family has a sense of itself as an emotionally connected group. Resources, including information, food, friends, or sources of energy, can impact the system, yet the system has ways of managing and monitoring its boundaries so that it is not overwhelmed by external forces. As energy or resources are used, the open system has ways of acquiring new resources from adjoining systems. An isolated system has a very tight, impermeable boundary that does not allow outside forces to enter. When the energy or resources of an isolated system are used up, it is difficult for the system to acquire new resources.

Adaptation is a fundamental process in system maintenance and change. A system uses **feedback** mechanisms to monitor and communicate among the elements within the system, and between the system and its environment. The more information about the environment the system is capable of detecting, the more complex these feedback mechanisms must be. For example, when the oxygen level of the environment is reduced, you tend to grow sleepy. While you sleep, your breathing slows, and you use less oxygen. This is a feedback mechanism that protects the system. Some adjustments are managed unconsciously by the organization of biological systems. Others are managed more deliberately by efforts to minimize the effects of environmental changes. Most systems have a capacity for storing or saving resources so that temporary shortages do not disrupt their operations. This is called **adaptive self-regulation**.

David Grossman/The Image Works

The neighborhood is a microsystem. Children adapt their play to the physical characteristics and resources of their neighborhood.

When open systems are confronted by new or changing environmental conditions, they have the capacity for **adaptive self-organization**. For example, when corporations have unexpected profits, they may create a new philanthropic arm to support some charitable goals, or create a new research and development wing to create new products. When an organization faces uncertainties related to new technologies or new markets, it may need to create new teams or redefine its goals. Similarly, when a family experiences illness of a family member, a person may withdraw from some aspect of work to spend more time with the person who is ill. When a child starts having new difficulties in school, parents may start to spend more time giving the child help with homework, or hire a tutor. The ability to withdraw from certain goals or to engage in new goals shows both aspects of adaptive self-organization (Wrosch, Amir, & Miller, 2011). In the face of change, the system retains its essential identity by creating new subsystems, revising the relationships among the components, or creating new, higher levels of organization that coordinate existing subsystems.

From the systems perspective, the components and the whole are always in tension. What one understands and observes depends on where one stands in this complex set of interrelationships. All living entities are both parts and wholes. A person is a part of a family, a classroom or work group, a friendship group, and a society. A person is also a whole—a coordinated, complex system composed of physical, cognitive, emotional, social, and self subsystems. Part of the story of human development is told in an analysis of the adaptive regulation and organization of those subsystems. Simultaneously, the story is told in the way larger systems fluctuate and impinge on individuals, forcing adaptive regulation and reorganization.

Ecological Systems Theory

In an effort to elaborate and clarify the set of interlocking systems in which human behaviors take place, Urie Bronfenbrenner (1979, 1995, 1999) developed ecological systems theory. According to this theory, individual development takes place in a complex set of interconnected systems, some of which the person is participating in directly, like the family, school, or workplace; and some of which impact the person indirectly because of the policies, resources, or expectations that influence the person's life. Four levels of systems are highlighted (see FIGURE 2.3 ▶):

1. A **microsystem** is a setting with particular physical characteristics and resources. Microsystems are characterized by patterns of activities, roles, and interpersonal relations experienced by the developing person. A child may function in multiple microsystems, such as a family, child care setting, and playground. One might expect that as people mature, they become involved in a larger number of microsystems with varying patterns of resources and expectations for behavior.
2. A **mesosystem** comprises the interrelations among two or more settings in which the developing person actively participates. For a child, this might be the relations among home, school, and neighborhood peer group. For an adult, this might be the relationships among family, work, community, and friendships. The demands of one setting, such as work, may require so much time and effort that the person is not able to meet expectations in another setting. Or the rewards of one setting are so highly valued that the person begins to neglect responsibilities in another setting.
3. An **exosystem** refers to one or more settings that do not involve the developing person as an active participant, but in which events occur that affect—or are affected by—what happens in the setting containing the developing person. A woman gets a promotion at work, which means more travel and time at corporate conferences. As a result, her partner has to spend more time at home caring for the children, and the children have fewer opportunities to interact with their mother. The partner and the children have no contact with the woman's work setting, but decisions made there have an impact on their lives.
4. The **macrosystem** refers to the culture or society that frames the structures and relationships among the systems. The macrosystem has laws and law enforcement practices, government agencies, social policies, health care resources, economic systems, educational resources, media, and many symbolic forms of influence that create the social, political, and financial contexts for development (Bronfenbrenner, 1979, pp. 22, 25, 26). For example, in 2007–2008, the United States experienced a major financial crisis. Many people lost their retirement savings, companies laid off tens of thousands of employees, and thousands of people experienced foreclosure on their homes. These events, brought about by mismanagement and greed at the macrosystem level, led to dramatic disruption at the family and community levels. The extreme and sudden nature of the financial losses required adaptive reorganization on the part of individuals and families as they disengaged from certain goals and re-engaged in alternatives.

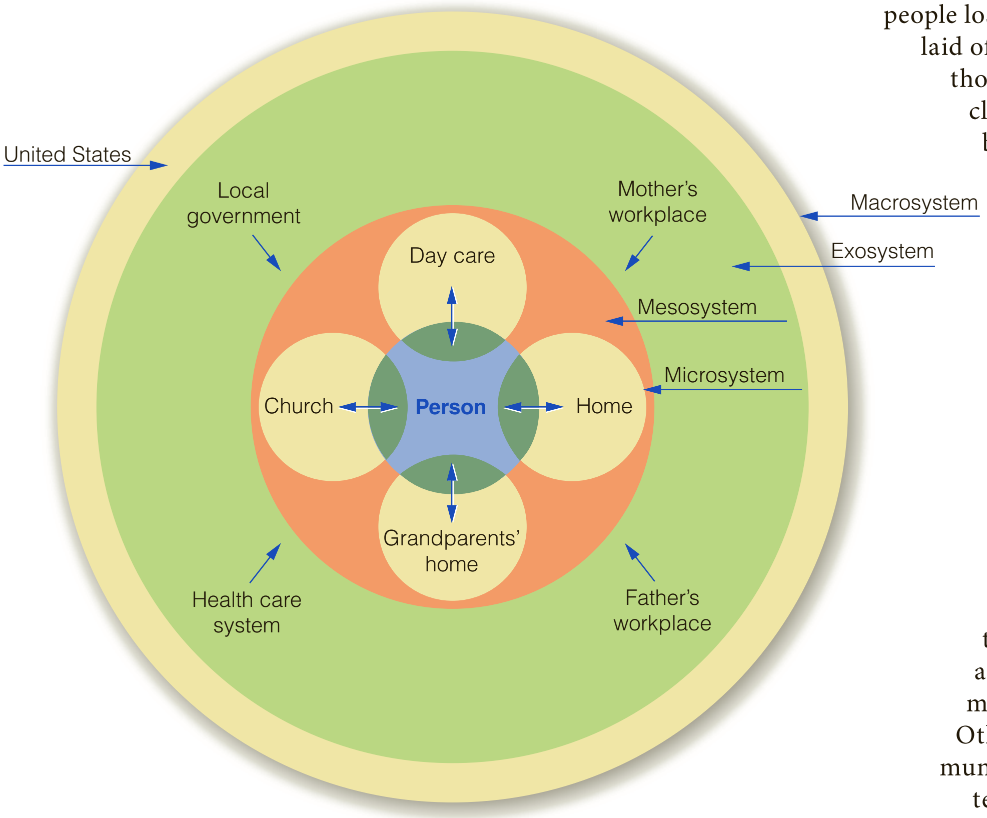

FIGURE 2.3 ▶ A TOPOGRAPHY OF THE RELATIONSHIP AMONG SYSTEMS This is a hypothetical model of a person's ecological contexts. Over time, the specific microsystems change, and a person becomes involved in new microsystems. The impact of previous systems may continue to influence a person as a result of learning, memories, and internalized values. The two-way arrows suggest that individuals influence their contexts and contexts influence the individuals who participate in them.

Source: Adapted from Bronfenbrenner, 1979.

Both the individual and the systems in which that person is embedded change over time. What is more, the relationships among the systems change over **time**. Some of these changes are patterned, developmental transformations, such as the change in a child's capacity for coordinated movement and voluntary, goal-directed action. Other changes are societal, such as a community decision to restructure a school system from an elementary (Grades K–6), junior high (Grades 7–9), and high school (Grades 10–12) system to an elementary (Grades K–5), middle school (Grades 6–8), and high school (Grades 9–12) system. Finally, some changes reflect the decline or improvement of resources in a setting over time, as when a neighborhood becomes transformed through urban development. As resources of an environment change, the setting may become more or less supportive of continuing development.

In his later writings, Bronfenbrenner modified his theory, focusing on the ways individuals influence their environments (Bronfenbrenner, 2004; Bronfenbrenner & Morris, 2006). Both personal characteristics such as intelligence, temperament, or physical appearance, and activities in which the person engages, such as social interactions, physical activities, or maintenance tasks, can modify the environment and alter its impact. Some people are more intentional than others about trying to alter their environments. Repeated efforts to alter one's environment may improve a person's ability to effect change.

In these writings, Bronfenbrenner emphasized the central role of processes as the basic engines that account for development. He described a **process** as any of a wide range of interactions between a person and the environment. These processes, which are activity based, connect the active, growing person with the people, objects and symbolic representations in the environment. In order for the processes to have an impact on development, they must take place frequently or regularly over relatively long periods of time. Over time, the maturing person may become engaged in the process in new ways, and the process itself may be modified to become more complex. Think about the process of reading books. In infancy, even before a baby can talk, a parent might read a book or two before bedtime. This process of reading begins as a time for physical closeness, shared attention, auditory and visual stimulation. With advancing development, infants can select books, turn pages, point to pictures, and imitate words and sounds from books. Reading becomes a cognitive process as the child recalls stories, selects favorite books, and pretends to read. The process of reading is gradually transformed from something initiated by an adult to something sought after and performed by the child.

Implications for Human Development

Systems theory has been applied to the study of the life span through **developmental systems theory** (Molenaar, Lerner, & Newell 2014). This perspective emphasizes the ongoing interaction and integration across many levels of the human organism from the genetic to the behavioral level. **Plasticity,** the capacity for change, is at the heart of this approach. The **person in the setting** is the focus of analysis. The challenge to developmental systems theory is to understand the **bidirectional** regulation of the person and the environment over time. How is the person shaped and defined by the contexts in which the person functions? How does the person influence these contexts to foster more optimal environments for growth?

The boundary between the person and the environment is fuzzy. As an open system, a person is continuously influenced by information and resources from the environment and, at the same time, creates or modifies the environment to preserve system functioning. In this view, the self is a flexible construct, constantly being modified by the nature of social roles, relationships and interactions.

> We carry on a whole series of different relationships to different people. We are one thing to one [*person*] and one thing to another . . . We divide ourselves up in all sorts of different selves with reference to our acquaintances. We discuss politics with one and religion with another. There are all sorts of different selves answering to all sorts of different social reactions. (Mead, 1934, p. 142)

A Systems View of Families

Systems theory has also been applied to the analysis of family functioning. Family systems theories focus on how families establish and maintain stable patterns of functioning. Families are viewed as emotional units identifiable by certain boundaries and rules (Broderick, 1993). The **boundaries** of the family determine who is considered to be a family member and who is an outsider. Some families have very strict **rules** that maintain a narrow boundary around the family. Few sources of information or contact are admitted. Other families extend the sense of belonging to a wide range of people who bring ideas and resources to the family system.

Family systems are maintained by patterns of communication (Vogl-Bauer, 2003). Positive and negative **feedback loops** operate to stabilize, diminish, or increase certain types of interactions. For example, a feedback loop is positive when a child offers a suggestion and a parent recognizes and compliments the child on that suggestion. As a result, the child is encouraged to continue to offer suggestions, and the parent comes to view the child as someone who has valuable suggestions to offer. A feedback loop is negative if a parent ignores the child's suggestions or scolds the child for making them. The child is less likely to make further suggestions, and the parents' view of the child as someone who has no valuable ideas to offer is confirmed. Many positive and negative feedback loops operate in families to sustain the qualities of the system, such as the power hierarchy, level of conflict, and balance between autonomy and dependence among the members.

One of the most commonly noted characteristics of family systems is the **interdependence** of the family members. Changes in one family member are accompanied by changes in the others. Imagine for a moment that family members are standing in a circle and holding a rope. Each person is trying to exert enough tension on the rope to keep it tight and preserve the circular shape. The amount of tension each person must exert depends on what every other person is doing. Now imagine that one member of the family lets go of the rope and steps away. In order to retain the shape and tension of the rope, everyone else has to adjust his or her grip. Letting go of the rope is an analogy for many kinds of changes that can occur in a family—a parent becomes ill, a child goes off to college, or a parent takes on a demanding job outside of the home. The system adjusts by redefining relationships, modifying patterns of communication, and adjusting its boundaries. The family systems perspective offers a distinct approach to clinical problems. A person who has been identified as dysfunctional is treated not as a lone individual, but as part of a family system. The assumption is that the person's problems are a product of the interactions among family members. The only way to bring about changes in that person's functioning is to alter the functioning of the *other* members of the system as well. If the person is underfunctioning—that is, acting irresponsibly, not communicating, not performing at a level of capability, withdrawing, or acting impulsively—one assumes that others in the family are overfunctioning—that is, assuming many of the person's roles and responsibilities in order to take up the slack. The dysfunctional behavior is maintained because it is a component of an emotional unit. Dysfunction belongs neither to the person nor to the other family members, but to the particular interdependence among the family members that operates to preserve the viability of the family system as a whole (Bowen, 1978; Gilbert, 2006).

Links to the Psychosocial Approach

The psychosocial approach is quite compatible with the basic assumption of systems theory—an understanding of development requires an analysis of the person embedded in a number of interrelated systems. Systems theory predicts that systems change through adaptive self-regulation and adaptive self-organization. The direction of this change is not necessarily patterned, except that it is expected to move in the direction of creating new, higher levels of organization to coordinate newly developed substructures. The nature of change is a product of efforts to retain a sense of system identity and boundaries in the face of multiple demands and shifts in environments.

According to psychosocial theory, however, change is patterned. At each new stage of life, a person is propelled into increasingly complex social systems and encounters new stimulation for growth through participation in a greater variety of social relationships. As they mature, individuals develop new coping skills and devise strategies for new levels of participation in the social system. Eventually, they create innovative approaches for modifying the social system itself.

Building on the assumption that development is a product of ongoing interactions between the person and society, the psychosocial approach suggests that both the diversity of microsystems in which one is embedded and the quality of one's connections to those microsystems will influence the direction of development. Feelings of belonging, attachment, and connection to particular microsystems are associated with lower levels of anxiety, depression, and antisocial behavior. For example, in a study of middle-school-age adolescents, those who had a positive connection to home, school, and neighborhood had better grades in school than those who had low connection to these contexts. A positive connection to at least one of these microsystems serves as a protective factor, providing a basis for self-esteem and a buffer against depression (Witherspoon, Schotland, Way, & Hughes, 2009). The specific configuration of microsystems and one's role or place in those systems contribute to the positive or negative direction of development over the life span.

CASE ANALYSIS Using What You Know

1. Explain the usefulness of the concept of a family system in trying to understand the relationship of Jack Manasky, his daughter Marilyn, and his deceased wife Anna.
2. Evaluate the feedback mechanisms between Jack Manasky and Marilyn. How does communication between these two family members encourage or discourage certain behaviors?
3. Hypothesize the ways that the macrosystem may influence Jack and Marilyn's approach to food, nutrition, and health.

CHAPTER SUMMARY

Table 2.9 provides an overview of the primary emphasis and aspects of development highlighted in each of the theories.

OBJECTIVE 1 Explain the concept of theory and discuss how theories contribute to the study of human development.

A theory is a logical system of concepts that helps explain observations and points to underlying processes or relationships that are not readily observable. In order to understand a theory, one must consider which phenomena the theory is trying to explain, the assumptions that underlie the theory, and the theory's predictions about causal relationships or systematic associations. A theory of human development typically addresses several of the following questions: What is the direction of change over the life span? What are the mechanisms that account for continuity and change? What is the relevance of early experiences for later development? How do physical, cognitive, emotional, and social functions interact? How do the physical and social environments impact development? What factors typically place the person at risk for problems in development at various periods of life?

The seven theoretical perspectives reviewed in this chapter each take a distinct approach to explaining continuity and change across the life span.

OBJECTIVE 2a Explain the basic concepts of the theory of evolution and examine its implications for the study of human development.

Evolutionary theory provides a framework for understanding individual development within the broad perspective of the biological evolution of the human species. Although a life span of 85 or 90 years may seem long, it is just a flicker in the millions of years of biological adaptation. Evolutionary theory highlights the genetically governed aspects of growth and development. The environment provides the specific conditions that require adaptation. However, adaptive change can occur only if it is supported by the genetically based characteristics of the organism. The basic mechanism that accounts for species change over many generations is natural selection.

Table 2.9 Overview of Seven Theories of Development

Theory	Emphasis	Specific Aspects of Human Development
Evolutionary theory	The emergence and modification of species as a result of natural selection	Fitness and inclusive fitness; the adaptive value of species' characteristics
Psychoanalytic theory	The origins and development of mental life	Personality development, emotions, motivation, impulse control, morality
Cognitive developmental theories	The origins and development of cognition	The development of reasoning and logical thought from infancy through adolescence; the role of culture and the teaching/learning process
Learning theories	The formation of relatively permanent changes in behavior as a result of experience	Learned behaviors, observational learning, the distinction between learning and performance, affects, expectancies, values, goals, and plans
Cultural theory	Learned systems of meanings and patterns of behavior shared by groups and transmitted from one generation to the next	The nature and direction of culturally guided developmental pathways; diversity in worldview
Social role theory	Socially constructed roles and role relationships that bridge the individual and society	The development of the self in social life; role gain, role loss, and the enactment of multiple roles
Systems theory	Processes that account for continuity and change in complex systems	The interdependence of elements within and between systems; emergence of new properties and behaviors as a result of self-regulation and self-organization; bidirectional nature of influence across system boundaries

© Cengage

Ethology, the study of evolutionarily significant behaviors, provides a systematic approach to analyzing reproductive practices, caregiving behaviors, strategies for obtaining resources, and other behaviors that contribute to individual and species survival. Evolutionary psychology focuses on understanding the human mind in terms of the problems of survival it has been shaped to solve.

OBJECTIVE 2b Explain the basic concepts of psychoanalytic theory and examine its implications for the study of human development.

According to psychoanalytic theory, development follows a biologically determined path in which patterns of social relationships change as a result of emerging sexual and aggressive impulses and the sexualization of body zones. Culture plays a major role in establishing the taboos and acceptable patterns of sexual gratification that lead to conflicts, fixations, and strategies for sublimation. The content of the unconscious—including sexual impulses, wishes, and fears—guides behavior and gives it meaning. Psychoanalytic theory emphasizes the years of infancy and childhood as those in which basic personality patterns are established. It also identifies the family, especially the parent–child relationship, as the primary context within which conflicts related to the socialization of sexual impulses are resolved. In contemporary psychoanalytic theory, interpersonal needs and the relational context of ego development are highlighted in contrast to the drive-based perspective of traditional psychoanalytic theory.

OBJECTIVE 2c Explain the basic concepts of cognitive developmental theories and examine their implications for the study of human development.

Cognitive developmental theories focus on the etiology of rational thought and the capacity for scientific reasoning. Piaget's cognitive theory, like psychoanalytic theory, views development as the product of a biologically guided plan for growth and change. The elements that make cognitive growth possible are all present in the genetic information that governs the growth of the brain and nervous system. However, the process of intellectual growth requires interaction with a diverse and responsive environment. Cognitive development is fostered by the recognition of discrepancies between existing schemes and new experiences. Through the reciprocal processes of assimilation and accommodation, schemes are modified and integrated to form the basis for organizing and explaining experience. The child is viewed as actively constructing knowledge through sensory, motor, and representational exploration.

Vygotsky's contribution to cognitive theory places the development of higher mental processes in a dynamic social context. Although thinking and reasoning are dependent on biologically based capacities, the way in which mental activity is organized reflects unique characteristics of the social context, especially as culture is transmitted through language, tools, and social relationships.

OBJECTIVE 2d Explain the basic concepts of learning theories and examine their implications for the study of human development.

Learning theories focus on the mechanisms that permit individuals to respond to their diverse environments and the changes in thought and behavior that accompany changes in the environment. Behavior can be shaped and modified by systematic changes in environmental conditions. According to learning theorists, human beings have an especially flexible behavioral system. No assumptions are made about universal stages of growth. As conditions in the environment change, response patterns also change. Similarity among individuals at a particular period of life is explained by the fact that they are exposed to similar environmental conditions, patterns of reinforcement, and models. Consistent contingencies between behaviors and their consequences result in the formation of cognitive expectations as well as behaviors.

OBJECTIVE 2e Explain the basic concepts of cultural theory and examine its implications for the study of human development.

Cultural theory, like the learning theories, emphasizes the role of the environment in directing the course of development. However, within the cultural theory framework, the focus is on the patterns of meaning that are given to biological maturation as well as the activities and routines that shape developmental pathways. Cultural theory recognizes certain constants in developmental tasks, but the ideal direction and socialization processes for guiding development differ widely across cultural groups. What one defines as the normal or natural pattern and tempo of change in competence, roles, and status depends largely on the way a society recognizes and treats individuals of different ages, sexes, and degrees of kinship.

OBJECTIVE 2f Explain the basic concepts of social role theory and examine its implications for the study of human development.

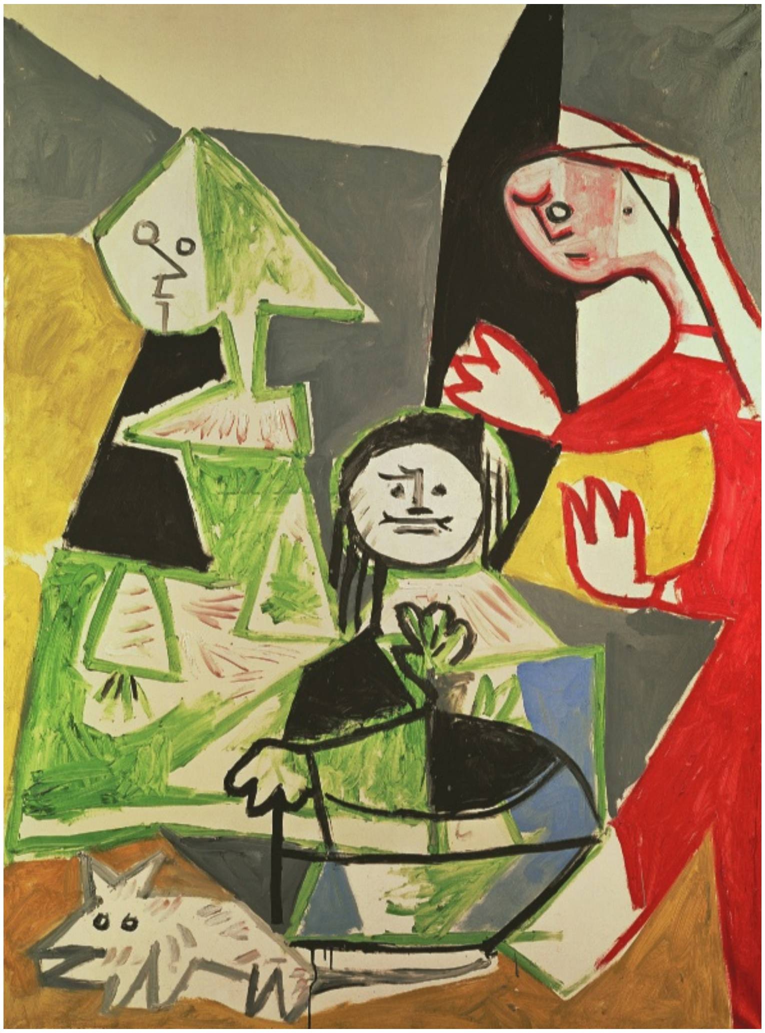
Social role theory suggests that learning is organized around key social functions called roles. As people enact roles, they integrate their behavior into meaningful units. Meaning is provided by the definition of the role and by the expectations of those in reciprocal roles. Development is a product of entry into an increasing number of complex roles over the life span. As children acquire and lose roles, they change their self-definitions and their relationships with social groups. Most societies define roles that are linked with gender, age, marital status, and kinship. These roles provide patterning to the life course. However, the patterns are understood to be products of the structures and functions of the society rather than of genetic information.

OBJECTIVE 2g Explain the basic concepts of systems theory and examine its implications for the study of human development.

Systems theory emphasizes the multidimensional sources of influence on individuals and the simultaneous influence of individuals on the systems of which they are a part. Each person is at once a component of one or more larger systems, and a system unto the self. One must approach the study of development from many angles, identifying the critical resources, the flow of resources, and the transformation of resources that underlie an adaptive process of reorganization and growth. This perspective has been applied to an analysis of families and family change as well as to individual development over the life span. Ecological systems theory highlights the layered nature of environments and the salient processes or activities that link individuals with their settings over time.

CASEBOOK

For additional case material related to this chapter, see the case of "A School Debate," on page 13 of *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman. This case focuses on the opinions of teachers and the school principal at a middle school about how to increase school attendance and reduce student tardiness. The varying suggestions reflect the application of different theories of human development to the solution of an important real-world problem. The case provides practice in linking theoretical ideas about causes of behavior to potential strategies for intervention.



The Family of Philip IV, no.42 from 'Las Meninas', 1957 (oil on canvas), Picasso, Pablo (1881-1973)/Museo Picasso, Barcelona, Spain/Bridgeman Images

This painting, The Family of Philip IV, no. 42, was inspired by the famous masterpiece Las Meninas, painted by Velázquez in 1656. Picasso first saw this painting when he was 14 years old. In 1957 he spent four months exploring many facets of the work, ultimately producing numerous interpretations. We are witnessing psychosocial evolution through art–the transmission of inspiration across centuries. Picasso's work conveys the intimacy of family life, adding a feeling of movement and chaos between adults and children as they try to get the little girl dressed for the day while the dog scampers underfoot. As implied in psychosocial theory, development is a product of ongoing interactions among people and their physical and social environments.

LEARNING OBJECTIVES

1. Explain the rationale for using psychosocial theory as an organizing framework for the study of human development.
2. Define the six basic concepts of psychosocial theory: stages of development, developmental tasks, psychosocial crisis, central process for resolving the crisis, radius of significant relationships, and coping.
3. Evaluate psychosocial theory, pointing out its strengths and weaknesses.

Chapter Summary

In this chapter we introduce the basic concepts of psychosocial theory that provide the integrating framework for our approach to the study of human development. Psychosocial theory accounts for patterns of individual development that emerge from a biopsychosocial process. The theory covers the entire life span from infancy through elderhood, offering a guide for thinking about essential life issues such as the importance of parent–infant interactions, the role of school in promoting a sense of competence, the emergence of a personal identity, the formation of loving relationships in adulthood, and the relationship of meaningful work to personal well-being. It provides concepts that help explain the complex interplay between individuals and their societies, including insights into understanding why some people soar and thrive while others struggle and withdraw.

The Rationale for Emphasizing Psychosocial Theory

OBJECTIVE 1 Explain the rationale for using psychosocial theory as an organizing framework for the study of human development.

We have selected **psychosocial theory** as an organizing framework for the text because of its range and scope. Having read chapter 2, you understand that psychosocial theory is not the only or most widely accepted theory for studying human development. However, it combines three features that make it especially useful as we strive to link the broad field of human development to applications in health, human services, education, and social welfare (Green, 2008):

1. Psychosocial theory addresses growth across the life span, identifying and differentiating central issues from infancy through elderhood.
2. Psychosocial theory assumes that individuals have the capacity to contribute to their own psychological development at each stage of life. People have the ability to integrate, organize, and conceptualize their experiences in order to protect themselves, cope with challenges, and direct the course of their lives. Therefore, the direction of development is shaped by self-regulation as well as by the ongoing interaction of biological and societal influences.
3. Psychosocial theory takes into consideration the active contribution of **culture** to individual growth. At each life stage, cultural goals, aspirations, and social expectations and requirements make demands that evoke individual reactions. These reactions influence which of a person's capabilities will be developed further. This vital link between the individual and the culture is a key mechanism of development. Each society has its own view of the qualities that reflect maturity. These qualities are infused into the lives of individuals and help determine the direction of growth within the society.

Ted Streshinsky Photographic Archive/Getty Images

Although Erik Erikson's name is typically associated with psychosocial theory, the work is a product of an active collaboration between Erik and his wife Joan.

The person who identified and developed psychosocial theory was Erik H. Erikson. He was initially trained as a psychoanalyst. His theory was influenced by the work of many others, including Sigmund and Anna Freud, Peter Blos, Robert White, Jean Piaget, and Robert Havighurst, whose ideas you will encounter throughout this book. His wife Joan was an important intellectual collaborator as well. Erik and Joan worked together to formulate the first presentation of psychosocial theory and its eight stages of development in 1950 (J. M. Erikson, 1988).

The case study, which was written by Erikson, gives us a brief look into his early life and leads us to speculate about how his life experiences may have guided the direction of his theoretical work. Just like other great thinkers of his time, being an outsider seems to have had some advantages for Erikson, allowing him to approach the study of human development from a unique, multidisciplinary and creative point of view (Dunbar, 2000).

The psychosocial approach that guides the organization of this book expands on Erikson's theory, integrating the literature in human development, especially the idea of developmental tasks, to help explain the multidimensional competences needed to address each of the psychosocial crises. The book also expands on the number of stages, including a focus on prenatal development, two stages of adolescence, and two stages of later life. These additions are a product of the growing body of evidence about the genetic and environmental factors that shape prenatal life, the increasingly complex nature of society that requires an extended period of adolescence, and the expanding length of life and the vitality of many who live well beyond their original life expectancy.

FURTHER REFLECTION *What is the focus or range of applicability of psychosocial theory? What is this theory about?*

— CASE STUDY Erik H. Erikson —

Erik Erikson (1902–1994) illustrates the psychosocial perspective by describing the personal, family, and societal factors that contributed to his own identity crisis.

There is first of all the question of origin, which often looms large in individuals who are driven to be original. I grew up in Karlsruhe in southern Germany as the son of a pediatrician, Dr. Theodor Homburger, and his wife Karla, née Abrahamsen, a native of Copenhagen, Denmark. All through my earlier childhood, they kept secret from me the fact that my mother had been married previously; and that I was the son of a Dane who had abandoned her before my birth. They apparently thought that such secretiveness was not only workable (because children then were not held to know what they had not been told) but also advisable, so that I would feel thoroughly at home in their home. As children will do, I played in with this and more or less forgot the period before the age of three, when mother and I had lived alone. Then her friends had been artists working in the folk style of Hans Thoma of the Black Forest. They, I believe, provided my first male imprinting before I had to come to terms with that intruder, the bearded doctor, with his healing love and mysterious instruments. Later, I enjoyed going back and forth between the painters' studios and our house, the first floor of which, in the afternoons, was filled with tense and trusting mothers and children. My sense of being "different" took refuge (as it is apt to do even in children without such acute life problems) in fantasies of how I, the son of much better parents, had been altogether a foundling. In the meantime, however, my adoptive father was anything but the proverbial stepfather. He had given me his last name (which I have retained as a middle name) and expected me to become a doctor like himself.

Identity problems sharpen with that turn in puberty when images of future roles become inescapable. My stepfather was the only professional man (and a highly respected one) in an intensely Jewish small bourgeois family, while I (coming from a racially mixed Scandinavian background) was blond and blue-eyed, and grew flagrantly tall. Before long, then, I was referred to as "goy" in my stepfather's temple; while to my schoolmates I was a "Jew." Although during World War I, I tried desperately to be a good German chauvinist, I became a "Dane" when Denmark remained neutral.

At the time, like other youths with artistic or literary aspirations, I became intensely alienated from everything my bourgeois family stood for. At that point, I set out to be different. After graduation from the type of high school called a humanistic Gymnasium . . . I went to art school, but always again took to wandering. . . . And in those days every self-respecting stranger in his own (northern) culture drifted sooner or later to Italy, where endless time was spent soaking up the southern sun and the ubiquitous sights with their grand blend of artifact and nature. I was a "Bohemian" then.

Source: Erikson, 1975.

CASE ANALYSIS Using What You Know

As you think about this autobiographical case, consider the following questions:

1. Describe why Erikson feels like a "stranger in his own culture."
2. Analyze the biological, psychological, and societal factors that contributed to Erikson's identity crisis.
3. Speculate about factors from childhood which appear to be influencing his experiences as an adolescent.
4. Evaluate the role of the significant figures in Erikson's life, the radius of significant others, and the parts they played in defining how he should behave and who he should strive to become.
5. Hypothesize about the factors that might have contributed to Erikson's ability to cope with the challenges of this period of his life, so that he could eventually discover a sense of direction and meaning.

Basic Concepts of Psychosocial Theory

OBJECTIVE 2 Define the six basic concepts of psychosocial theory: stages of development, developmental tasks, psychosocial crisis, central process for resolving the crisis, radius of significant relationships, and coping.

Psychosocial theory offers an organizational framework for considering individual development within the larger perspective of psychosocial evolution. **Psychosocial evolution**, a construct proposed by Julian Huxley (1941, 1942), refers to the human abilities that allow us to gather knowledge from our ancestors and transmit it to our descendants. Childrearing practices, education, and modes of communication are examples of mechanisms that transmit information from earlier generations to the present time. Meanwhile, new information, new ways of thinking, and new ways of teaching are developed. The transmission of values and knowledge across generations requires the maturation of individuals who are capable of creating knowledge, symbolizing it, adapting it, and transferring it to others.

Psychosocial theory accounts for systematic change over the life span using six basic concepts: (1) stages of development, (2) developmental tasks, (3) psychosocial crises, (4) central processes for resolving the crisis at each stage, (5) networks of significant relationships, and (6) coping—the process through which people generate new behaviors to meet new challenges. These concepts will be defined in the following sections. However, each concept includes stage-specific content that will be discussed in greater detail in subsequent chapters. Table 3.1 provides an

overview of the life stages, summarizing the content of the basic concepts for each stage of life. In addition, for each stage there is a discussion of an applied topic of current interest that illustrates how a psychosocial perspective can help us to analyze the topic and shape directions for action.

Take a moment to study the table. You can use it as a guide and study aid to help identify the major themes of the text. It may help you to see the connections among the topics in a chapter and to trace threads of continuity over several periods of life. You may also use this table in constructing a life map for yourself that will reveal areas of emerging competence, potential tension, and the major psychosocial factors that are currently affecting your self-concept and your relationships with others.

Stages of Development

A **developmental stage** is a period of life that is characterized by a specific underlying organization. At every stage, some characteristics differentiate that stage from the preceding and succeeding stages. Stage theories propose a specific direction for development. At each stage, the accomplishments from the previous stages provide resources for mastering the challenges of the new stage. Each stage is unique and leads to the acquisition of new skills related to new capabilities. In the process of development, it is not uncommon to observe plateaus, where the level of competence remains steady while the person integrates new abilities, followed by a spurt of rapid reorganization as the person attains a new, more complex level of functioning (Dawson-Tunick, Commons, Wilson, & Fischer, 2005).

Within the framework of psychosocial theory, the concept of stages of development refers to a pattern of changes in the self-concept based on new cognitive capacities, new learning, and the acquisition of new relationship skills. At each stage, the biological, psychological, and societal systems converge around a set of defining challenges that require a new view of the self in society and a new way of relating to others (Whitbourne, Sneed, & Sayer, 2009). You can verify the stage concept through reflection on your own past. You can probably recall earlier periods when you were very preoccupied by efforts first to gain your parents' approval, then to win acceptance by your peers, and later to experience self-acceptance. Each of these concerns may have appeared all-encompassing at the time, but eventually each gave way to a new preoccupation. At each stage, you were confronted with a unique set of problems that required the integration of your personal needs and skills with the social demands of your culture.

Erikson (1963) proposed eight stages of psychosocial development. His formulation can be traced in part to the stages of psychosexual development proposed by Freud and in part to his own observations and rich mode of thinking. FIGURE 3.1 ▶ shows the chart that Erikson (1963) produced in *Childhood and*

	1	2	3	4	5	6	7	8
Oral–sensory 1	Basic trust vs. mistrust							
Muscular–anal 2		Autonomy vs. shame, doubt						
Locomotor–genital 3			Initiative vs. guilt					
Latency 4				Industry vs. inferiority				
Puberty and adolescence 5					Identity vs. role confusion			
Young adulthood 6						Intimacy vs. isolation		
Adulthood 7							Generativity vs. stagnation	
Maturity 8								Ego integrity vs. despair

Erikson, 1963.

FIGURE 3.1 ▶ ERIKSON'S MODEL OF THE PSYCHOSOCIAL STAGES OF DEVELOPMENT

Society to describe the stages of psychosocial development. The shaded boxes identify the main psychosocial conflicts of each stage. If the conflict of a stage is handled well, a new sense of mastery and competence emerges. In Erikson's original model, the periods of life are given names, such as oral–sensory or puberty and adolescence, but no ages. This approach reflects Erikson's emphasis on an individual timetable for development, guided by both biological maturation and cultural expectations rather than by a strict chronological time frame for development.

Erikson (1963) proposed that the stages of development follow the **epigenetic principle**—a biological plan for growth that allows each function to emerge systematically until the fully functioning organism has developed. An assumption of this and other stage theories is that the stages form a sequence. Although one can anticipate challenges that will occur at a later stage, one passes through the stages in an orderly pattern of growth. In the logic of psychosocial theory, the entire life span is required for all the functions of psychosocial development to appear and become integrated. There is no going back to an earlier stage because experience makes retreat impossible. In contrast to other stage theories, however, Erikson suggested that one can review and reinterpret previous stages in the light of new insight or new experiences.

Furthermore, the themes of earlier stages may reemerge at any point. Through reflection and insight, a person can find new meaning and new resolutions to earlier conflicts. Joan Erikson reflects on the fluidity and hopefulness in this perspective:

> This sequential growth . . . is now known to be more influenced by the social milieu than was in previous years considered possible. . . . Where a strength is not adequately developed according to the given sequence for its scheduled period of critical resolution, the supports of the environment may bring it into appropriate balance at a later period. Hope remains constant throughout life that more sturdy resolutions of the basic confrontation may be realized. (J. M. Erikson, 1988, pp. 74–75)

Lawrence Migdale/Science Source

The epigenetic principle assumes that it takes the entire life span, from the prenatal period through elderhood, for all facets of human capacity to emerge. In later adulthood and elderhood grandparents transmit the wisdom of their generation to their grandchildren by teaching them stories, songs, customs, and beliefs.

The concept of life stages permits us to consider the various aspects of development, such as physical growth, social relationships, and cognitive capacities, at a given period of life and to speculate about their interrelation. It also encourages a focus on the experiences that are unique to each life period—experiences that deserve to be understood both in their own right and for their contribution to subsequent development. When programs and services are designed to address critical needs in such areas as education, health care, housing, and social welfare, the developmental stage approach allows the designers to focus on the needs and resources of the particular population to be served.

Despite the usefulness of a stage approach, one must avoid thinking of stages as pigeonholes. Being in a given stage does not mean that a person cannot function at other levels. It is not unusual for people to anticipate later challenges before they become dominant. Many children of toddler and preschool age, for example, play house, envisioning having a husband or a wife and children. You might say that, in this play, they are anticipating the issues of intimacy and generativity that lie ahead. The experience of having a child—whether this occurs at age 18, 25, or 35—is likely to raise issues of generativity, even if the theory suggests that this theme is not in its peak ascendancy until middle adulthood. Whereas some elements of each psychosocial theme can be observed at all ages, the intensity with which they are expressed at certain times marks their importance in the definition of a developmental stage. Erikson, Erikson, and Kivnick (1986) put it this way:

> The epigenetic chart also rightly suggests that the individual is never struggling only with the tension that is focal at the time. Rather, at every successive developmental stage, the individual is also increasingly engaged in the anticipation of tensions that have yet to become focal and in re-experiencing those tensions that were inadequately integrated when they were focal; similarly engaged are those whose age-appropriate integration was then, but is no longer, adequate. (p. 39)

As one leaves a stage, the achievements of that period are neither lost nor irrelevant to later stages. Important ego strengths emerge from the successful resolution of conflicts at every stage. Some of these strengths may be challenged or reorganized as events take place later in life that call into question the essential beliefs established in an earlier period. For example, the psychosocial conflict during early school age is initiative versus guilt. Its positive outcome, a sense of initiative, is a joy in innovation and experimentation and a willingness to take risks in order to learn more about the world. Once achieved, the sense of initiative provides a positive platform for the formation of social relationships and for further creative intellectual inquiry and discovery. However, experiences in a highly authoritarian school environment or in a very judgmental, shaming personal relationship may inhibit one's sense of initiative or mask it with a facade of indifference.

The concept of the psychosocial stages of development is very good as far as it goes, but Erikson's road map seems incomplete. Three criticisms of this layout of the life span have been raised. First, although the boxes in the figure look very even and comparable, each stage is actually of very different length. Second, the figure suggests discrete shifts from one stage to the next, when in fact the themes of these stages overlap (McAdams & de St. Aubin,1992). Transitions from stage to stage are not instantaneous. Movement from one stage to the next is the result of changes in several major systems that take place gradually. Third, if the idea of psychosocial evolution has validity—and we believe it does—new stages can be expected as a culture evolves.

In this text, we have identified 11 stages of psychosocial development, each with the following approximate age range: (1) *prenatal*, from conception to birth; (2) *infancy*, from birth to 2 years; (3) *toddlerhood*, 2 to 4 years; (4) *early school age*, 4 to 6 years; (5) *middle childhood*, 6 to 12 years; (6) *early adolescence*, 12 to 18 years; (7) *later adolescence*, 18 to 24 years; (8) *early adulthood*, 24 to 34 years; (9) *middle adulthood*, 34 to 60 years; (10) *later adulthood*, 60 to 75 years; and (11) *elderhood,* 75 until death.

By discussing a prenatal stage, two stages of adolescent development rather than one, and elderhood, we are adding three stages to those proposed by Erikson. This revision is a product of our analysis of the research literature, observations through research and practice, discussions with colleagues, and suggestions from other stage theorists. The addition of these three new stages provides a good demonstration of the process of theory construction.

FIGURE 3.2 ▶ shows the 11 stages of psychosocial development as presented in this textbook. The age range given for each stage is only an approximation. Each person has a uniquely personal timetable for growth. Differences associated with poverty, health, cultural group (e.g., differing rates of longevity), and exposure to environmental risks also lead to different timetables. The lengths of the stages vary, from the 9 months of the prenatal period to the roughly 26 years of middle adulthood.

FURTHER REFLECTION *Explain how psychosocial theory treats biological maturation and experience as forces guiding development.*

Evaluate the concept of stages of development. How might this concept prove useful in the contexts of education, counseling, or human services?

Developmental Tasks

Robert J. Havighurst first introduced the concept of **developmental tasks**. He believed that human development is a process in which people attempt to learn the tasks required of them by the society to which they are adapting. These tasks change with age because each society has **age-graded expectations** for behavior. As Havighurst observed, "Living in a modern society is a long series of tasks to learn" (1972, p. 2). In Havighurst's view, the person who learns well receives satisfaction and reward; the person who does not suffers unhappiness and social disapproval.

Although Havighurst's view of development emphasized the guiding role of society in determining which skills need to be acquired at a certain age, he did not totally ignore the role of physical maturation. Havighurst believed that there are **sensitive periods** for learning developmental tasks—that is, times when the person is most ready to acquire a new ability. Havighurst called these periods **teachable moments**. Most people learn developmental tasks at the time and in the sequence appropriate in their society. If a particular task is not learned during the sensitive period, it may be much more difficult to learn later on.

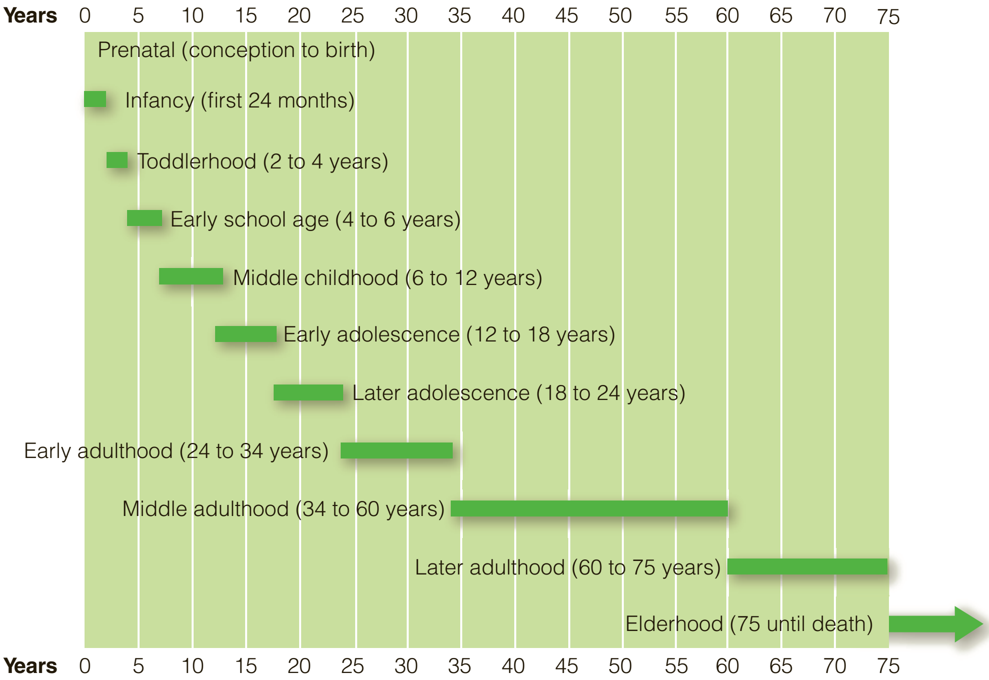

FIGURE 3.2 ▶ THE 11 STAGES OF THE LIFE SPAN

Source: Erikson, 1963.

At each stage of life, one faces new developmental tasks that contribute to increased mastery over one's environment. These tasks reflect areas of accomplishment in physical, cognitive, social, and emotional development, as well as development of the self-concept. The specific tasks we identify differ from those outlined in Havighurst's writings. Our choice of tasks is based on broad areas of accomplishment that have been identified by researchers as critical to psychological and social growth at each stage of life in a modern, technological culture.

We often think of mastery of developmental tasks, especially in childhood, as being fostered as parents and teachers encourage, educate, and model new levels of functioning for their children and students. However, as they move into early adolescence, young people are increasingly likely to invent novel strategies to advance their competence. The Internet provides a rich and diverse environment in which adolescents explore interests, form and strengthen social relationships, and find outlets for the expression of their opinions (Borca, Bina, Keller, Gilbert, & Begotti, 2015).

Societal expectations for mastery of a developmental task may change over time. These changes may be gradual, occurring over generations. For example, we identify emotional development as a task that begins in infancy and is a focus of attention again in early adolescence. The content of this task changes markedly across developmental stages, and society has changed in its expectations about the nature of this task. Lauren, an American Indian mother describes how her approach to emotional expression with her children differs from the way she was raised:

> We are more open with our children; we allow them to express themselves, a lot more than we were allowed as children ourselves. Basically, if we had something to say, we felt like we wanted to say something about our emotions, we were like told, "I don't want to hear anything about that " You know, we were not given a voice. Whereas children today are not only given a voice, but are given plenty of opportunity to express that voice. (Parker et al., 2012, p. 77)

Changing societal expectations that impact developmental tasks may also occur rapidly, as happened during the radical political transformation of the 1990s in many countries of central and eastern Europe and the former Soviet Union. Young people experienced new freedoms that encouraged more autonomy of expression, travel, and political engagement. They also faced new challenges related to employment and economic uncertainties. These societal changes did not alter the importance of basic developmental tasks of adolescence and early adulthood, but led to a postponement of the timing of traditional transitions into family and career roles (Tomasik & Silbereisen, 2012).

The basic premise associated with the concept of developmental tasks, regardless of their specific content, is that a relatively small number of major psychosocial challenges dominate a person's problem-solving efforts and learning during a given stage of life. As these tasks are mastered, new competencies enhance the person's ability to engage in more complex social relationships and advanced problem solving. Effective mastery of the developmental tasks of a specific stage of life provides building blocks for mastery of the tasks of future stages (Masten, Obrdovic, & Burt, 2006; McCormick, Kuo, & Masten, 2011).

Courtesy of Philip Newman

Toddlerhood is a sensitive period for language development, when parent–child conversations are especially critical.

Successful cultures will stimulate behavior that helps its members learn what they need to know for both their own survival and that of the group. In the case presented earlier in the chapter, Erikson provides an example of how the culture supports a person's work on the developmental tasks of a particular life stage. As he was entering later adolescence following graduation from Gymnasium, Erikson took advantage of a culturally accepted period of exploration by traveling to Italy. During this period, he was able to work on several of the developmental tasks of later adolescence, especially gaining greater autonomy from his family, experimenting with possible career paths, and clarifying his values and beliefs by becoming a "Bohemian."

Keep in mind that a person is maturing in a few important domains at once during each period of life. Tasks involving physical, emotional, intellectual, and social growth, as well as growth in one's self-concept, all contribute to one's resources for dealing with the challenges of life. Table 3.2 shows the developmental tasks we have identified as areas of learning for most people in modern society and the stages during which each set of tasks is of primary learning value. There are 42 developmental tasks on the list. Whereas the infant is learning orientations and skills related to the first 5, a person at the

Table 3.2 Developmental Tasks Associated with the Life Stages

Life Stages*	Developmental Tasks
Infancy (first 24 months)	Maturation of sensory/perceptual and motor functions Sensorimotor intelligence: Processing, organizing, and using information Communication Attachment Emotional development
Toddlerhood (2 to 4)	Elaboration of locomotion Language development Fantasy play Self-control
Early school age (4 to 6)	Gender identification Early moral development Self-theory Peer play
Middle childhood (6 to12)	Friendship Concrete operations Skill learning Self-evaluation Team play
Early adolescence (12 to18)	Physical maturation Formal operations Emotional development Membership in the peer group Romantic and sexual relationships
Later adolescence (18 to 24)	Autonomy from parents Gender identity Internalized morality Career choice
Early adulthood (24 to 34)	Exploring intimate relationships Childbearing Work Lifestyle
Middle adulthood (34 to 60)	Managing a career Nurturing an intimate relationship Expanding caring relationships Managing the household
Later adulthood (60 to 75)	Accepting one's life Redirecting energy toward new roles and activities Promoting intellectual vigor Developing a point of view about death
Elderhood (75 until death)	Coping with physical changes of aging Developing a psychohistorical perspective Traveling through uncharted terrain

*We do not consider the concept of developmental tasks appropriate to the prenatal stage.

© Cengage

early adulthood stage has already acquired skills related to 27 tasks from the previous stages. New learning may continue in these areas as well as in the 4 new developmental tasks faced by the young adult. This helps one appreciate that by the time people reach early adulthood, they have a considerable repertoire of competencies that can be used to cope with the challenges of life. By the stage of elderhood a person has all the areas of previous learning to draw from while working on three new tasks.

FURTHER REFLECTION *Describe a developmental task that may have changed in content or focus from the time of your grandparents to your parents or from your parents to you. What are some of these changes? What may have led to these changes?*

Psychosocial Crisis

A **psychosocial crisis** refers to a state of tension that results from the discrepancies between the person's competences at the beginning of a stage and the society's expectations for behavior at that period of life (Erikson, 1963). For example, in toddlerhood, the second stage of development from roughly ages 2 to 4, the psychosocial crisis is autonomy versus shame and doubt. At the beginning of this stage, the toddler may have established a strong, positive, and trusting relationship with the caregiver. Now the child is expected to function more independently, to take care of some basic needs, and exercise new levels of self-control. These expectations for new levels of autonomy may be accompanied by new experiences of shame. A child may overreach by asserting too much autonomy.

> In an attempt to do something on her own, Mindy tries to pour her own glass of milk from the carton and spills milk all over the counter. Her mother says, "What a mess! You should have waited for me to help you."
>
> On the other hand, a child may be shamed for being overly dependent.
>
> Brad is trying to get Lewis ready for preschool. They have to leave by 8:00 a.m. in order to get there on time. Lewis is just sitting on the floor, playing with his Legos. "Lewis, I need you to get your shoes on so we can get going. You are old enough to do this on your own. You shouldn't need me to remind you every morning about how to get ready to go."

At each developmental stage, the sense of crisis arises because one must make psychological efforts to adjust to the demands of the social environment. The word *crisis* in this context refers to a normal set of stresses and strains rather than to an extraordinary set of events.

Societal demands vary from stage to stage. People experience these demands as mild, but persistent expectations for behavior. They may be demands for greater self-control, further development of skills, or a stronger commitment to goals. Before the end of each stage of development, the individual tries to achieve a resolution, adjust to society's demands, and at the same time translate those demands into personal terms. This process produces a state of tension that the individual must reduce in order to proceed to the next stage.

Mastery of the developmental tasks and resolution of the psychosocial crises interact to produce individual life stories. The skills learned during a particular stage as a result of work on its developmental tasks provide the tools for the resolution of the psychosocial crisis of that stage. This resolution orients the person toward new experiences, a new aptitude for relationships, and new feelings of personal worth as the challenges of the next stage's developmental tasks begin.

Psychosocial Crises of the Life Stages

Table 3.3 lists the psychosocial crisis of each stage of development from infancy through elderhood. This scheme, derived from Erikson's model shown in Figure 3.2, depicts the crises as polarities—for example, trust versus mistrust, and autonomy versus shame and doubt. These contrasting conditions suggest the underlying dimensions along which each psychosocial crisis is resolved. According to psychosocial theory, most people experience both positive and negative elements of the continuum. For example, even within a loving, caring family environment that promotes trust, an infant will experience some moments of frustration or disappointment that result in mistrust.

The outcome of the crisis at each stage is an integration of the two opposing forces. For each person, the relative frequency and significance of positive and negative experiences will contribute to a resolution of the crisis. The likelihood of a completely positive or a completely negative resolution is small. Most individuals resolve the crises in a generally positive direction, supported by a combination of positive experiences and natural maturational tendencies. At each successive stage, however, the likelihood of a negative resolution mounts as the developmental tasks become more complex and the chances of encountering societal barriers to development increase.

To understand the process of growth at each life stage, we have to consider the negative as well as the positive pole of each crisis. The dynamic tension between the positive and negative forces reflects the struggles a person encounters to restrain powerful impulses, overcome fears and doubts, and look past one's own needs to consider the needs of others.

Table 3.3 The Psychosocial Crises

Life Stage*	Psychosocial Crisis
Infancy (first 24 months)	Trust versus mistrust
Toddlerhood (2 to 4)	Autonomy versus shame and doubt
Early school age (4 to 6)	Initiative versus guilt
Middle childhood (6 to 12)	Industry versus inferiority
Early adolescence (12 to 18)	Group identity versus alienation
Later adolescence (18 to 24)	Individual identity versus identity confusion
Early adulthood (24 to 34)	Intimacy versus isolation
Middle adulthood (34 to 60)	Generativity versus stagnation
Later adulthood (60 to 75)	Integrity versus despair
Elderhood (75 until death)	Immortality versus extinction

*We do not consider the concept of psychosocial crisis appropriate to the prenatal stage.

© Cengage

In every psychosocial crisis, experiences at both the positive and negative poles contribute to the total range of a person's adaptive capacities. Although a steady diet of mistrust is undesirable, for example, it is important that a trusting person be able to evaluate situations and people for their trustworthiness. This ability is based in part on experiences of mistrust, which help a person recognize cues about safety or danger in any encounter.

Why conceptualize life in terms of crises? Does this idea adequately portray the experience of the individual, or does it overemphasize conflict and abnormality? The term *crisis* implies that tension and conflict are necessary to the developmental process; crisis and its resolution are viewed as normative, biologically based components of life experience at every stage.

The term *psychosocial* draws attention to the fact that the crises are, in part, the result of cultural pressures and expectations. Individuals will experience tension because of the culture's need to socialize and integrate its members. The concept acknowledges the dynamic conflicts between individuality and group membership at each period of life.

Looking back to the opening case, Erikson attributes the psychosocial crisis around his personal identity to a convergence of biological, psychological, and societal factors. He is physically different from his Jewish family members; he is identified as a religious outsider by his friends; and he is an object of traditional, middle-class family values and expectations that he rejects. As he emerges into later adolescence, he finds his transitional identity as an artist, an identity that he explores for several years before discovering his potential as a teacher, therapist, and theorist.

The exact nature of the psychosocial crisis is not the same at each stage. However, as reflected in the epigenetic principle, the succession of crises occurs in a predictable sequence over the life course. Although Erikson did not specify the exact ages for each crisis, the theory hypothesizes an age-related progression, in which each crisis has its time of special significance. The research described in the **Applying Theory and Research to Life** box Using Autobiographical Memories to Explore Psychosocial Stages of Life illustrates one approach for exploring the empirical basis of this concept.

Unforeseen Crises

In addition to the predictable psychosocial crises, any number of unforeseen stressors may arise. These stressors may impact individuals and families, such as parental divorce, death of a sibling, or unexpected job loss. Unforeseen crises may extend more broadly to communities or nations, as in national disasters, acts of terrorism, famine, or war. Although these events may foster growth and new competencies, they may also result in anxiety, defensiveness, regression, or dread. The need to cope with them may overwhelm a person and may require coordinated intervention. For example, experts from eight European countries have formed a consortium to provide guidelines on mental health and psychosocial support for people in crisis. Their work is especially targeted for people in communities that have been exposed to natural or man-made disasters. Interventions are designed to consider the special needs of children, adolescents, disabled

APPLYING THEORY AND RESEARCH TO LIFE

Using Autobiographical Memories to Explore Psychosocial Stages of Life

Psychosocial theory predicts that the self-concept and worldview are reorganized at each stage of life to highlight new goals and a new relationship of self and society. To explore this idea further, Martin Conway and Alison Holmes (2004) asked adults between the ages of 62 and 89 to recall memories for each decade of their lives from the first 10 years through the decade of the 60s. The participants were asked about the decades in a random order and were given 5 minutes per decade to write down up to three memories from that time of life. Each memory was dated to the nearest year and month within the decade. The memories were then coded for the degree to which they reflected themes inherent in the psychosocial crises.

Fifty participants produced 552 memories. The two decades from ages 10 to 19 and 20 to 29 produced the largest number of memories (FIGURE 3.3 ▶). As predicted, memories tied to early psychosocial crises (wanting to be or being nurtured, helped, and taught; having fun and playing; encounters with parents, family members, and teachers) were most frequently recalled in association with the first decade of life. Memories associated with identity and identity confusion were most frequent in the second decade of life. Memories related to intimacy were of greatest frequency in the third decade. In contrast to childhood memories that decline noticeably from the first decade of life, memories associated with generativity increased gradually from the 20s to the 40s and continued to be prominent in the decades of the 50s and the 60s. Relatively few memories were coded as reflecting the themes of integrity and despair, but those memories were tied primarily to the decade of the 60s. These findings use biographical memory recall to support the view that the self is reorganized around different goals and preoccupations at various stages of life that reflect the demands and satisfactions associated with the psychosocial crises of those stages.

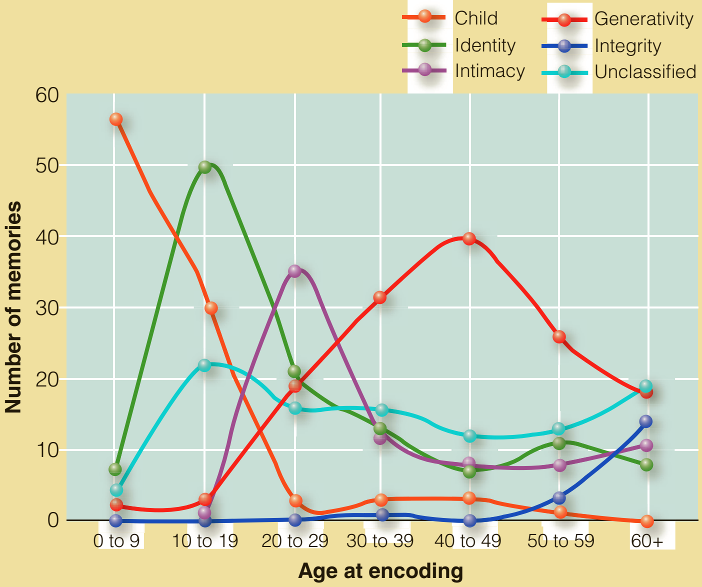

FIGURE 3.3 ▶ LIFE-SPAN MEMORY DISTRIBUTION CURVES FOR MEMORIES CLASSIFIED BY PSYCHOSOCIAL STAGE OVER SEVEN DECADES OF LIFE

Critical Thinking Questions

1. Evaluate the strengths and limitations of using autobiographical memory to study psychosocial development over the stages of life.
2. Given the detailed conceptualization of psychosocial theory presented in this chapter, propose a list of additional variables you might want to measure in order to determine the salience of specific psychosocial crises at various periods of life.
3. Describe other approaches to measurement you might use aside from memory recall to study the question of patterns of psychosocial development.

individuals, and the elderly. This work is also sensitive to the mental health and psychosocial needs of volunteers and first responders (OPSIC, 2015).

The impact of an unpredictable crisis will depend in part on whether the person is in a state of psychosocial crisis at the time. For example, the unexpected death of a sibling might be exceptionally disruptive for someone who is also in a period of questioning their personal identity, where matters of family loyalties and commitments to values and beliefs are unresolved. A person who has resolved the psychosocial crisis in a positive direction is likely to have greater resilience and ego strength to cope with this difficult loss (Svetina, 2014).

The combination of predictable crises, unpredictable crises, and unique historical pressures may lead to the resurfacing of prior crises that require reorganization. For example, during early adulthood, when issues of intimacy versus isolation are most important, it is common to find a reworking of industry versus inferiority as well. While striving to form

The devastating earthquake in Nepal left ruins in Kathmandu city, resulting in death, injury, and homelessness. 800,000 homes were damaged or destroyed. Children, adults, and the aged cope differently with these unexpected crises; communities differ in their ability to reassure and rebuild.

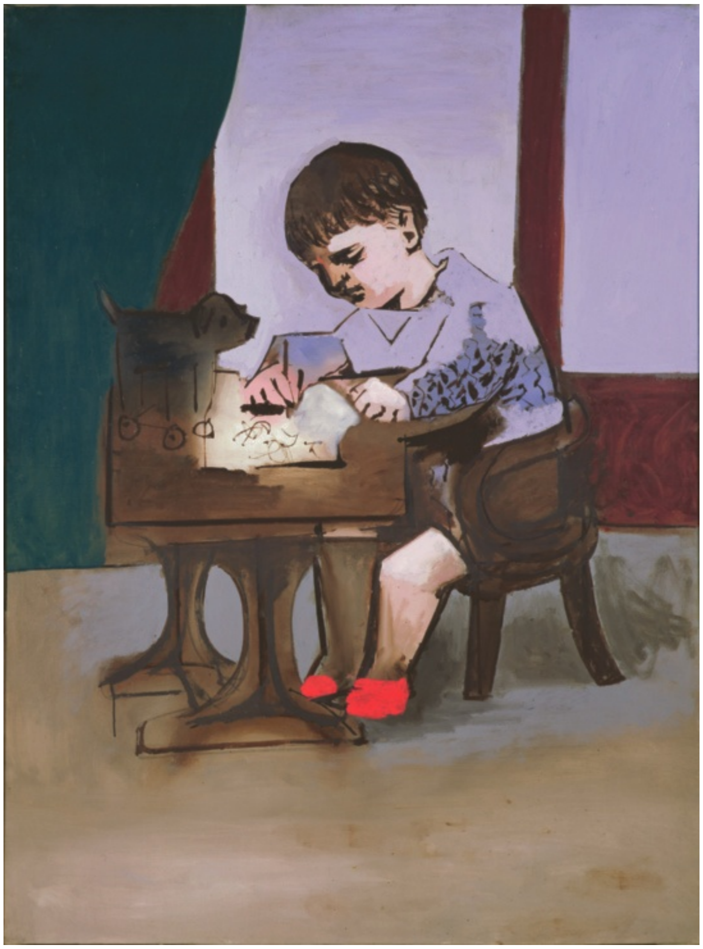
meaningful, close relationships, young adults also encounter the challenges of establishing themselves in the labor market and achieving self-sufficiency. The outcome of this reworking of an earlier crisis depends in part on historical factors, such as the economic and materialistic orientation of the society as a specific age group enters early adulthood. It also depends on additional individual factors—especially on whether the adult is able to forge a meaningful occupational role that is consistent with personal and community values (Thomasik & Silbereisen, 2012; Whitbourne, Sneed, & Sayer, 2009). Thus, the psychosocial crises are not resolved and put to rest once and for all. Each crisis is played and replayed both during ongoing developmental changes and when life events challenge a balance that was achieved earlier.

FURTHER REFLECTION *What is the psychosocial crisis associated with your current stage of life? What thoughts and feelings can you identify that relate to these themes? How do these thoughts and feelings impact your self-concept and your relationships with others?*

The Central Process for Resolving the Psychosocial Crisis

Every psychosocial crisis reflects some discrepancy between the person's developmental competencies at the beginning of the stage and new societal pressures for more effective functioning. How is the discrepancy resolved? What experiences or processes permit the person to interpret the expectations and demands of society and to internalize them in order to support change? We have identified a **central process** through which each psychosocial crisis is resolved. The central process suggests a way that the person takes in or makes sense of cultural expectations and, as a result, changes the self-concept. The term **process** refers to an ongoing operation or activity, which may not be directly observable, that takes place in small increments over time and leads to a natural transformation. This concept is similar to Bronfenbrenner's use of the term to refer to basic mechanisms that connect an active, growing person with the people, objects, and symbolic representations in the environment as discussed in chapter 2. In the physical world, we are familiar with processes such as evaporation, condensation, and breathing. In psychosocial theory, each central process suggests a means by which the person recognizes new social pressures and expectations, gives these expectations personal meaning, and gradually changes.

The process, unfolding over time, results in a new relationship between self and society. For example, in toddlerhood, the psychosocial crisis raises the question of how children increase their sense of autonomy without risking too many experiences that provoke a sense of shame and doubt. We suggest that **imitation** is the central process for psychosocial growth during toddlerhood (ages 2 to 4). Children expand their range of skills by imitating adults, siblings, television models, playmates, and even animals. Movement toward a sense of autonomy in toddlerhood is facilitated by the child's readiness to imitate the variety of



Peter Willi/SuperStock

Pablo Picasso's son is shown in deep concentration as he sketches at his desk. Through imitation, a child takes ownership of actions and skills that are observed when among adults. It is little wonder that Paulo, surrounded by his father's ongoing artistic activity, would be drawn to imitate it.

Table 3.4 The Central Process for Resolving Each Psychosocial Crisis

Life Stage*	Central Process
Infancy (first 24 months)	Mutuality with caregiver
Toddlerhood (2 to 4)	Imitation
Early school age (4 to 6)	Identification
Middle childhood (6 to 12)	Education
Early adolescence (12 to 18)	Peer pressure
Later adolescence (18 to 24)	Role experimentation
Early adulthood (24 to 34)	Mutuality among peers
Middle adulthood (34 to 60)	Person–environment fit and creativity
Later adulthood (60 to 75)	Introspection
Elderhood (75 until death)	Social support

*We do not consider the concept of central process appropriate to the prenatal stage.

models available for observation, and the variety of behaviors the child has the opportunity to observe. Through persistent imitative activity, children expand their self-initiated behavior and control over their actions. Repetitive experiences of this kind allow children to believe that they can do more things on their own; this advances their sense of personal autonomy.

The central process for coping with the challenges of each life stage provides both personal and societal mechanisms for taking in new information and reorganizing existing information. It also suggests the means that are most likely to lead to a revision of the psychological system so that the crisis of that particular stage can be resolved. Each central process results in an intensive reworking of the psychological system, including a reorganization of boundaries, values, and images of oneself and others. Table 3.4 shows the central process that leads to the resolution of the psychosocial crisis at each life stage.

Radius of Significant Relationships

Age-related demands on individuals are communicated through **significant relationships** (Erikson, 1982, p. 31) (see FIGURE 3.4 ▶). Initially, a person focuses on a small number of relationships. During childhood, adolescence, and early adulthood, the number of relationships expands, and the quality of these relationships takes on greater variety in depth and intensity. In later adulthood, the person often returns to a small number of extremely important relationships that provide opportunities for great depth and intimacy. Figure 3.4 suggests that each layer in the radius of significant relationships is a neat circle of individuals. But in fact, the circles are comprised of complex **networks** of individuals who interact with each other as well as with the target person. You might think of these circles as intermingling vines, much like holiday wreaths, where people from various families, neighborhoods, and groups communicate. This network of relationships plays a major role at every stage of life, impacting cognitive and emotional development, self-understanding, family and career roles, and physical health.

> Mildred, a woman in her late 70s, is an active, retired professor of mathematics. She lives alone but with family and friends nearby. In the spring, she had a stroke. Luckily, her son was able to get her to the hospital quickly. After some days of hospitalization, she returned home. She was surrounded by family and friends who came to visit, brought books and movies, food, and good conversation to speed along her convalescence. She had a strong and positive relationship with her family doctor. By September, she was almost fully recovered and back to her active life.

FIGURE 3.4 ▶ THE RADIUS OF SIGNIFICANT RELATIONSHIPS

Source: © Cengage

In Erikson's case study, he recalls a network of artists who may have influenced him at a very early age while he was living with his mother. Then, the radius of significant relationships shifted to include his father, Dr. Homburger, who was a trusted and respected professional. As he moved into later adolescence, he found a network of like-minded young people with artistic and literary ambitions who supported his feelings of alienation from his traditional family and offered a milieu of acceptance and care. Subsequently he became immersed in a network of professional analysts who educated and trained him and offered him a new professional identity.

At each stage of life, the network of significant relationships determines the demands that will be made, how the person will be taken care of, conflicts the person is exposed to, and the meaning that could be derived from these relationships. The quality of these relationships is determined in part by the psychosocial maturity of the people who populate these networks. Often, the people in these relationships serve as role models and resources for the developing person. However, in some cases, the person experiences significant relationships that are intrusive, negative, or undermining to optimal development. For example, some children experience harsh, intimidating interactions with parents, grandparents, older siblings, or peers. As a result, the developing person may learn to be aggressive with others. Some children experience interactions with adults who are very self-absorbed and narcissistic. As a result, they may learn not to expect much from others. The point is that the quality of the interactions in this radius of significant relationships transmits information about how the person is valued and what to expect in social exchanges. The relationship network varies individually, but each person has a network of significant relationships and an increasing readiness to enter into a more complex social life (Christakis & Fowler, 2009). The quality of these relationships and the norms for interaction are influenced by the nature of the specific social context. Family, culture, and ethnic group are three of the major network contexts through which the radius of significant relationships transmits its influences. In addition to these historically acknowledged contexts, there is growing interest in how social media, including Facebook, Twitter, Instagram, and other cyber technologies, have become contexts for social influence.

Contexts of Development

One way of thinking about the impact of the societal system is to consider individuals as embedded in a kaleidoscope of changing, interconnected systems. Children are members of families. Parents and other relatives are members of other important work and community groups that can influence families. As they get older, children may become members of other institutions, such as child care programs, schools, religious groups, community clubs, or athletic teams. Communities are nested in cities, counties, states, and nations. An understanding of development requires insight into each level of social organization as well as the culture as a whole. These organizations influence what is expected of its members, the resources available to meet these expectations, the roles individuals play, the activities they engage in, and the risks they may encounter.

The **contexts of development** include social, economic, and historical factors. Events such as war, political revolution, famine, or economic collapse may temporarily alter the prevailing childrearing values, opportunities for education or employment, and the availability of resources. Furthermore, these events may increase exposure to violence and separation of family members or provide exposure to other unpredictable stressors that may disrupt the course of development.

Families. All over the world, children are raised by small groups or families. Family is the universal primary social context of childhood. The family continues to be a meaningful context throughout life, especially as we think of the relationship of adults with their aging parents, the formation of new families in adulthood, and the lifelong connections among siblings. Historically, the term **family** has referred to a group of people, usually related by blood, marriage, or adoption. In contemporary U.S. society, however, people who view themselves as members of a family may have no legal relationship or shared ancestral bond. The composition and nature of the relationships among members of modern families is diverse. The psychosocial meaning of family, however, continues to be defined as individuals who share a common destiny and who experience a sense of emotional intimacy. Ideally, people in a family care about one another and take care of one another (Price, Price, & McKenry, 2010). As we see throughout the book, there are vast differences in the ways family members define their roles and treat one another.

Culture. Culture refers to the socially standardized ways of thinking, feeling, and acting that are shared by members of a

Courtesy of Philip Newman

As a newborn, Max is the center of a radius of significant relationships, including his mother, father, older brother, grandparents, aunts, and uncles.

society. Culture includes the concepts, habits, skills, arts, technology, religion, and government of a people. It encompasses the tools and symbol systems that give structure and meaning to experience. Cultures have implicit theories about the stages of life, the expectations for behavior as one matures, and the nature of one's obligations to the older and younger members of the cultural group. A culture exerts influence directly through families as well as through networks of interacting individuals who may belong to common social organizations such as churches, clubs, or schools. As is true for other nations, the United States' culture has a strong, unifying impact on its citizens. Within the United States, there are also noticeable regional cultural patterns marked by unique vocabulary and dialect, mannerisms, and styles of social interaction. Throughout this book, we will note the great differences in what life—including family life—is like in different cultures and note how the integration of person and culture produces distinctive personal experiences for individuals in various cultures.

Ethnic Groups. In addition to the common threads of culture that affect everyone who grows up or lives for a long time in the United States, there are also persistent subcultural forces that shape the daily lives of children and adults. The United States is a complex society made up of people from a vast array of cultures throughout the world. We call these groups ethnic subcultures or **ethnic groups**. People who belong to ethnic groups share ways of thinking, feeling, and acting with other members of their group. Holidays such as St. Patrick's Day, Oktoberfest, or Kwanzaa are examples of public occasions that celebrate the ethnic heritage of particular groups.

Research has focused on the development of ethnic identity, particularly the ways in which one's ethnic heritage and cultural values are integrated into one's personal identity. Ethnic values may include views about family cohesiveness, the importance of certain religious practices, the role and meaning of education, attitudes toward elders, or efforts to preserve a language and customs. The influence of one's ethnic heritage is likely to change from one generation to another. Studies examine the role of ethnic values and beliefs for first-generation immigrants as compared to second- and third-generation offspring (Coll & Marks, 2009; Portes & Rumbaut, 2014). Increasing attention is being given to the lifestyles, identity development, parenting practices, and family values of ethnic groups, particularly the challenges facing immigrants to the United States as they strive to integrate their cultural and ethnic beliefs and practices into contemporary U.S. life (Coll & Marks, 2012).

Many people in the United States acknowledge mixed ethnic ancestry, resulting in experiences of ambiguous and/or multi-ethnic identities (Ho, 2015). According to the U.S. Census Bureau, the population reporting mixed racial heritage (9.0 million) grew by 32.0 percent from 2000 to 2010 (Jones & Bullock, 2012). Thus, a person's radius of significant relationships may include people who convey diverse cultural, religious, and/or ethnic values, some of which are more salient or comfortably integrated than others. In subsequent chapters we will address the contributions of ethnicity and mixed ethnicity to developmental pathways.

Social Media. Evidence about the impact or influence of social media on development is contradictory. Some studies find that people who use social media frequently feel more connected, whereas other studies find that the frequent use of social media is associated with stress, reduced feelings of happiness, and stronger feelings of loneliness and depression (Barth, 2015; Brooks, 2015). These differences may relate to the motivation for engaging in the use of social media. Many people make use of social media to stay connected to their family and friends, especially when they are separated by distance. They are preserving and strengthening their existing radius of significant relationships. Others use social media primarily as a way to connect to like-minded others whom they do not know in a face-to-face relationship (Murthy, Gross, & Pensavalle, 2015). Social media can also be used l to promote one's business or to foster one's professional reputation. Still others use social media for dating, to spread gossip, or to try to establish their popularity within their peer culture.

Social media are contexts through which individuals create and are influenced by their radius of significant relationships. People get more excited, pleased and rewarded by being recognized among their social media contacts; and more discouraged, depressed, and hurt by being rejected, ignored, or maligned by their contacts (Barth, 2015).

Social networking sites can provide information in order to make social comparisons (Vogel, Rose, Okdie, Eckles, & Franz, 2015). By checking in with "friends" on Facebook or following people on Twitter, a person can assess whether his or her daily life, accomplishments, and/or adventures are as successful or thrilling as those of others. Some students describe their preoccupation with social media as linked to a fear of missing out on the fun, gossip, or plans that are being formulated among their peers. Some people are more prone to seek social comparison than others, needing more reassurance and feedback in order to feel confident about their worth. As a result they are more likely to make frequent use of their social media contexts, trying to reduce their anxiety and self-doubt (Nesi & Prinstein, 2015). Many adolescents and adults "follow" television and movie stars, athletes, or popular music artists on social media. This kind of connection may strengthen their identification with these role models, providing a stronger bond of influence. Some of these media personalities offer advice through blogs on parenting, financial decisions, career advice, or political views, which can influence the beliefs and values of their "followers."

Coping

Coping refers to people's conscious, adaptive efforts to manage stressful events or situations and their efforts to manage the emotions associated with these stressors (Aldwin, 2011). Coping is a process that begins with an **appraisal** of the situation. This includes answers to the following questions: What is the nature of this stressor? How much of a threat is it? How much time do I have to deal with this challenge? How much control do I have over the situation?

Following the appraisal, one must enlist cognitive, affective, and behavioral **coping strategies** to manage the stress. Lazarus and Folkman (1984) distinguished between coping strategies that intend to change something about the source of stress (*problem-focused coping*) and strategies that intend to manage or control one's emotions in the face of the stressor (*emotion-focused coping*). Often, these strategies are used together.

> For example, Claire, who has taken a week of vacation, has returned to work to find a basket full of mail, 40 voice messages, and 180 email messages. She still has her usual daily workload. She decides to take a short lunch and stay an hour late in order to catch up. At the same time, she tries to remain calm and think about the wonderfully relaxing time she had on her vacation so that she does not become anxious as she faces this backlog of work. She uses both problem-focused and emotion-focused strategies to manage the demands of this situation.

In order to understand how a person copes with a stressful situation, one must consider (1) the nature of the stressor, (2) how it is perceived by the person, and (3) the range of resources that are available to address the situation (Hobfoll, 2011; Lazarus, 2000; McCubbin & Patterson, 1982). The coping process depends on the specific stressful situation. One does not cope the same way if the house is on fire or if the baby has a high fever. In the situation of bereavement, for example, there are no actions the grieving person can take to bring the lost loved one back to life. Survivors must find ways to reconcile themselves to the situation and carry on with their own lives. Depending on the circumstances of the loss, survivors need to develop effective coping strategies in order to preserve their health, and continue to form meaningful ties with others (Stroebe, 2011; Wortman & Boerner, 2007).

One's approach to coping also depends on the values, beliefs, and goals of the person or family involved and how these values, beliefs, and goals lead to a particular interpretation of the stressor event. For example, in one family, the announcement that an oldest child decides to enlist in the military may be greeted with great joy and pride; in another family, that same announcement may be greeted with dismay and disappointment. Both families will worry about the child's safety and will experience the stress of the child's absence. However, the family's beliefs and goals will determine the meaning given to a child's decision to join the military.

Finally, individuals and families differ in the resources that are available to cope with a difficult situation. Resources include such things as social support, educational background, information, professional advice, financial resources, and a sense of humor. In the research literature, the term **socioeconomic status (SES)** is used to refer to a combination of resources including income, education, and occupation. Fewer resources, or the lack of appropriate resources, may impede the coping process. In a study exploring how people cope with financial stress, problem-focused coping was found to be more effective in reducing distress than emotion-focused coping (Caplan & Schooler, 2007). Among those participating in this study, those with fewer social and economic resources (referred to as low SES) were found to use more emotion-focused coping strategies and, as a result, had higher levels of distress. The path from low SES to distress over financial strain is brought about largely through perceived lack of control, which interferes with the mobilization of problem-focused coping.

Coping behavior is an important concept in psychosocial theory because it explains how unique and inventive behaviors occur. An important aspect of coping is the ability to redefine or *reappraise* the situation in a positive way. This suggests creating or reemphasizing the meaning, values, and opportunities embedded in the stressful situation (Folkman & Moskowitz, 2000).

> For example, as Robert cared for his partner who had AIDS, he took special pleasure in routine, daily events such as planning an enjoyable meal that they shared together. In the face of feelings of helplessness about the uncontrollable changes in his partner's condition, Robert also took steps to set attainable goals, such as creating a video library of favorite movies that he and his partner could enjoy together. Thus, even while Robert was experiencing many negative emotions, he also found positive experiences in the context of the stress.

Some people are better able to cope with the challenges they are faced with than others. The term **resilience** is often used to characterize individuals who exhibit positive outcomes in the face of serious threats to development. They may have experienced prolonged, severe poverty; they may have a parent with a serious mental illness; or they may have been exposed

Jim West/Alamy Stock Photo

Despite significant physical challenges, these young men are coping by developing new skills and engaging in competitive sports. Their sense of competence contributes to feelings of well-being and joy in life.

to ongoing abuse or violence. Faced with these or other difficulties, resilient individuals show low levels of psychological symptoms and function effectively in the basic developmental tasks expected for their stage of life (Masten, Obradović, & Burt, 2006). Over time, they create lives that integrate their own personal strengths with the resources and opportunities of their community, meeting the community's expectations for maturity. Although the story of resilience is highly individual, reflecting unique patterns of life challenges and coping strategies, the notion of resilience underscores a widely shared capacity to recover from adversity. There appears to be a small number of factors that support resilience including "connections to competent and caring adults in the family and community; cognitive and self-regulation skills; positive views of self; and motivation to be effective in the environment" (Masten, 2001, p. 13).

Over time, effective coping contributes to development. As a result of experiencing mastery and competence through coping, one builds a more positive expectation about being able to face new challenges, an outlook that contributes to the positive resolution of subsequent psychosocial crises. The positive consequences of coping help to sustain individuals during prolonged stressors. In the face of threat, coping behavior allows an individual to act effectively, rather than merely to maintain equilibrium or become disorganized.

New coping strategies can be learned. You will recall that approaches to coping with difficult emotions is a focus of cognitive behavioral therapy (See chapter 2). The goal of this therapy is to teach clients to examine unwanted ways of reacting to stressful situations and to develop new ways of reacting. This includes examining troubling situations with a degree of calm detachment, examining the facts of the situation, and using new information to formulate a new interpretation of the situation. Each of these strategies can be learned with practice and repetition. Over life, a person encounters new stressors that require new coping strategies. There is no single coping strategy that is appropriate for every situation. But a first step is learning to be calm so that you can apply your best rational strategies to the assessment of the situation. Learning to recognize whether a difficult situation can be changed, or one's interpretation and reaction to the situation must change, is a lifelong challenge.

According to psychosocial theory, at each stage of life, consistent efforts to face and cope with the psychosocial crisis of the period result in the formation of basic adaptive capacities, referred to as the **prime adaptive ego qualities**. When coping is unsuccessful and the challenges of the period are not adequately mastered, individuals are likely to form maladaptive orientations, referred to as **core pathologies**.

Prime Adaptive Ego Qualities

Erikson (1978) postulated prime adaptive ego qualities that develop from the positive resolution of the psychosocial crisis of a given stage and provide resources for coping with the next. He described these qualities as *mental states* that shape the interpretation of life experiences. The idea of adaptive ego qualities suggests that a person's core beliefs about the self are positive, well grounded in meaningful social relationships, and useful for interpreting real life events. Ego strengths support resilience in the face of stressors and position the person to make effective choices as they face new societal demands.

The prime adaptive ego qualities and their definitions are listed in Table 3.5. These ego qualities contribute to the person's dominant **worldview**, which is continuously reformulated to accommodate new ego qualities. With maturity, as one makes positive resolutions of each psychosocial stage, the ego strengths accumulate and become integrated. The person becomes increasingly hopeful, purposeful, competent, and committed to relationships and ideals. These strengths contribute to the way the person makes meaning and adapts to life conditions.

The importance of many of the prime adaptive ego qualities, including hope, purpose, competence, love, and wisdom, has been verified by research (Lopez & Snyder, 2003). For example, a measure, *The Psychosocial Inventory of Ego Strengths*, was developed to assess the relationship of the prime adaptive ego strengths to psychosocial well-being. As anticipated, higher scores on the psychosocial inventory were correlated with identity achievement, self-esteem, locus of control, empathic concern, and perspective taking (Markstrom, Sabino, Turner, & Berman, 1997; Markstrom & Marshall, 2007).

Focusing specifically on the ego quality of *hope,* Erikson and his colleagues found that people in later life who were hopeful about their own future and that of their children were more intellectually vigorous and psychologically resilient than those who were less hopeful (Erikson et al., 1986). People with a hopeful attitude have a better chance of maintaining their spirits and strength in the face of crisis than people who are pessimistic. For both young and older adults, the ego strength of hope has been found to be a significant predictor of life satisfaction (Isaacowitz, Vaillant, & Seligman, 2003).

Core Pathologies

Although most people develop the prime adaptive ego qualities, a potential core pathology may also emerge as a result of ineffective, negatively balanced resolution of the psychosocial crisis at each stage (Erikson, 1982; see Table 3.5). Like the prime adaptive ego qualities, core pathologies also serve as guiding orientations for behavior. These pathologies move people away from others, tend to prevent further exploration of interpersonal relations, and obstruct the resolution of subsequent psychosocial crises. As the core pathologies accumulate, the person becomes more withdrawn, compulsive, and inhibited. Fearfulness and self-doubt may lead to an increasingly rigid approach to life challenges. The energy that would normally be directed toward mastering the developmental tasks of a stage is directed instead toward resisting or avoiding change.

The core pathologies are not simply passive limitations or barriers to growth. They are energized worldviews leading to strategies that protect people from further unwanted association with the social system and its persistent, tension-producing demands. These strategies may find expression in attitudes that are rejecting and disdainful of others in efforts to disguise undermining negative feelings such as social rejection, disconnectedness, or lack of worth.

Table 3.5 Prime Adaptive Ego Qualities and Core Pathologies

Life Stage	Ego Quality and Core Pathology	Definition
Infancy (first 24 months)	Hope	An enduring belief that one can attain one's deep and essential wishes
	Withdrawal	Social and emotional detachment
Toddlerhood (2 to 4)	Will	A determination to exercise free choice and self-control
	Compulsion	Repetitive behaviors motivated by impulse or by restrictions against the expression of impulse
Early school age (4 to 6)	Purpose	The courage to imagine and pursue valued goals
	Inhibition	A psychological restraint that prevents freedom of thought, expression, and activity
Middle childhood (6 to 12)	Competence	The free exercise of skill and intelligence in the completion of tasks
	Inertia	A paralysis of action and thought that prevents productive work
Early adolescence (12 to 18)	Fidelity to others	The ability to freely pledge and sustain loyalty to others
	Dissociation	An inability to connect with others
Later adolescence (18 to 24)	Fidelity to values	The ability to freely pledge and sustain loyalty to values and ideology
	Repudiation	Rejection of roles and values that are viewed as alien to oneself
Early adulthood (24 to 34)	Love	A capacity for mutuality that transcends childhood dependency
	Exclusivity	An elitist shutting out of others
Middle adulthood (34 to 60)	Care	A commitment to concern about what has been generated
	Rejectivity	Unwillingness to include certain others or groups of others in one's generative concern
Later adulthood (60 to 75)	Wisdom	A detached yet active concern with life itself in the face of death
	Disdain	A feeling of scorn for the weakness and frailty of oneself and others
Elderhood (75 until death)	Confidence	A conscious trust in oneself and assurance about the meaningfulness of life
	Diffidence	An inability to act because of overwhelming self-doubt

FURTHER REFLECTION *Explain the concept of coping in your own words. Examine an example of problem-focused coping that you have observed in yourself or others. Describe how the actions influenced the outcome of the situation.*

Hypothesize how people at different stages of psychosocial development might cope with the same life stressor such as unemployment or the death of a parent.

Imagine that a teacher or social worker has identified a child who exhibits evidence of one or more core pathologies, such as withdrawal, compulsion, or inhibition. What steps can the concerned adult take to help alleviate or modify these characteristics?

Evaluation of Psychosocial Theory

OBJECTIVE 3 Evaluate psychosocial theory, pointing out its strengths and weaknesses.

Although we believe that psychosocial theory provides a useful theoretical framework for organizing the vast array of observations in the field of human development, we recognize that it has weaknesses as well as strengths. As a student of development, you must begin to form your own independent judgment of its usefulness. The strengths and weaknesses of psychosocial theory that are discussed in the following sections are listed in Table 3.6.

Strengths

Psychosocial theory highlights the social nature of human development. Human beings depend for their survival on their capacity to form social bonds and to recognize and respond to social messages. Although the field of psychology has traditionally focused on the thoughts and behaviors of individuals, a growing body of research emphasizes the social nature of mental functioning. Thus, the basic view of development offered by psychosocial theory as a product of interactions between the individual and the social environment is gaining increasing support.

Psychosocial theory provides a broad, integrative context within which to study life-span development (Hopkins, 1995; Kiston, 1994). The theory links the process of child development to stages of adult life, individual development to the nature of culture and society, and the personal and historical past to the personal and societal future. Although many scholars agree that such a broad perspective is necessary, few other theories attempt to address the interplay between individual development and society (Miller, 2011).

Table 3.6 Strengths and Weaknesses of Psychosocial Theory

Strengths	Weaknesses
The theory provides a broad, integrative framework within which to study the life span.	Explanations for the mechanisms of crisis resolution and process of moving from one stage to the next need to be developed more fully.
The theory provides insight into the directions of healthy development across the life span.	The idea of a specific number of stages of life and their link to a genetic plan for development is disputed.
Many of the basic ideas of the theory have been operationalized using traditional and novel approaches to assessment.	The theory and much of its supporting research have been dominated by a male, Eurocentric perspective that gives too much emphasis to individuality and not enough attention to connection and social relatedness.
The concept of psychosocial crises, including the positive and negative poles of the crisis, offers a model for considering individual differences within a framework of normal development.	The specific ways that culture encourages or inhibits development at each stage of life are not clearly elaborated.
The concept of the psychosocial crisis identifies predictable tensions between socialization and maturation.	
Longitudinal studies support the general direction of development hypothesized by the theory.

Source: Based on Erikson, 1982.

Psychosocial theory provides a framework for tracing the process through which self-concept, self-esteem, and self-other boundaries become integrated into a positive, adaptive, socially engaged person (Hamachek, 1985, 1994). Emphasizing the normal, hopeful, and creative aspects of coping and adaptation, the theory has taken the study of development beyond the deterministic position of psychoanalytic theory or the mechanistic view of behaviorism, providing an essential conceptual framework for the emergence of positive psychology.

Some have argued that a weakness of psychosocial theory is that its basic concepts were presented in language that is abstract and difficult to examine empirically (Crain, 2011; Miller, 2016). However, over the past 20 years, such terms as *hope, inhibition, autonomy, personal identity, intimacy, generativity,* and *integrity*—to name a few—have been operationalized (Bohlin, Bengtsgard, & Andersson, 2000; Christiansen & Palkovitz, 1998; de St. Aubin, McAdams, & Kim, 2003; Kroger, 2007; Lopez & Snyder, 2003; Marcia, 2002, 2007; McAdams & de St. Aubin, 1998; Snyder, 2002). Concepts central to the theory—such as trust, autonomy, identity achievement, coping, well-being, social support, and intergenerational interdependence—have become integrated into contemporary human development scholarship. Researchers have created instruments to trace the emergence of psychosocial crises and their resolution in samples varying in age from adolescence to later adulthood (Constantinople, 1969; Darling-Fisher & Leidy, 1988; Domino & Affonso, 1990; Hawley, 1988; Markstrom & Marshall, 2007; Waterman & Whitbourne, 1981; Whitbourne et al., 1992; Whitbourne et al., 2009).

Unlike some other theories, psychosocial theory identifies tensions that may disrupt development at each life stage, providing a framework for considering individual differences in development. The positive and negative poles of each psychosocial crisis offer a way of thinking about differences in self-concept development at each stage of life as well as a model for considering cumulative differences across the life span. This matrix of crises and stages provides a useful tool for approaching psychotherapy, counseling, and social work. Recent applications are directed toward leadership development and executive training. In a business context, for example, the concept of generativity highlights the importance of contributing to the development and mentoring of younger workers by their more senior supervisors in order to ensure the continuity of leadership for the organization.

The concept of normative psychosocial crises is a creative contribution that identifies predictable tensions between socialization and maturation throughout life. Societies, with their structures, laws, roles, rituals, and sanctions, are organized to guide individual growth toward a particular ideal of mature adulthood. However, every society faces problems striving to balance the needs of the individual with the needs of the group. All individuals face some strains as they attempt to experience their individuality while maintaining the support of their groups and attempting to fit into their society. Psychosocial theory offers concepts for exploring these natural tensions.

Longitudinal research using psychosocial theory as a framework for studying patterns of personality change and self-concept development has found support for many of its basic concepts. Changes in psychological outlook that reflect the major themes of the theory—such as industry, identity, intimacy, and generativity—appear to emerge and become consolidated over time (Whitbourne et al., 2009). There is also evidence of a preview of themes prior to their period of maximum ascendancy (Peterson & Steward, 1993) and evidence for the notion of revisitation through which adults are stimulated to rework and reorganize the resolutions of earlier issues (Shibley, 2000).

Weaknesses

One weakness of psychosocial theory is that the explanations of the mechanisms for resolving crises and moving from one stage to the next are not well developed (Miller, 2016). Think of Lillian who is 19 years old, has a close, loving relationship with a partner, is expecting her first child but has not yet settled on a career and lives with her parents. We can think of Lillian as straddling the boundary between later adolescence and early adulthood. Having made commitments regarding her partner and parenthood, does she already perceive herself as well grounded in the period of adulthood or is she still struggling with ambiguity regarding her personal identity?

The theory does not offer a universal mechanism for crisis resolution or a detailed picture of the kinds of experiences that are necessary at each stage if one is to cope successfully with the crisis of that stage. We have addressed this weakness by including the concepts of developmental tasks and a central process for each stage. The developmental tasks suggest some of the major achievements that permit a person to meet the social expectations of each stage. The central process identifies the primary mechanism through which the person encounters societal expectations and integrates them into a revised sense of self. Using these two constructs, one can begin to clarify the process of movement from one stage to the next.

The specific number of stages and their link to a biologically based plan for development has been criticized. The stages of life unfold in a cultural context. For example, in some societies, the transition from childhood to adulthood is swift, leaving little time or expectation for identity exploration. In many traditional societies, parents choose one's marital partner, there are few occupational choices, and one is guided toward one's vocation from an early age. Thus, although there is always a biological period of pubescence that marks the transition from childhood to adulthood, there may be little justification for two stages of adolescence when the identity formation process is societally constrained (Thomas & Schwarzbaum, 2011). In contrast, in our highly technological society, adolescence appears to be extended for some, especially as the age at first marriage is delayed and the complexity of preparing for and entering the labor market increases. As a reflection of this extension of modern adolescence, we have treated the period from puberty through about age 24 as two stages rather than one, each with its own psychosocial crisis and developmental tasks.

Along this same line of criticism, some scholars have taken a more differentiated view of the stages of adulthood and later life. In later life, health status, life circumstances, and culture interact to produce increasing variation in life stories. Distinctions are made between people of the same chronological age who are referred to as the "young-old" and the "old-old" depending upon their health status and their capacity to manage tasks of daily life (Aldwin, Spiro, & Park, 2006; Poon & Harrington, 2006).

In other research, distinctions are made on the basis of chronological age. For example, Leonard Poon has written extensively about the differences between centenarians (people who are 100 or more), octogenarians (people in their 80s), and sexagenarians (people in their 60s). Each cohort of older adults has been exposed to different historical crises, educational, health, and occupational opportunities, and shifting societal values. Therefore, it is likely that the normative patterns used to describe development in adulthood and later life will become outdated and need reexamination as each younger cohort enters later adulthood and elderhood (Randall, Martin, Bishop, Johnson, & Poon, 2012; Siegler, Poon, Madden, & Welsh, 1996).

We have addressed this concern in part by extending the traditional psychosocial stage approach to adulthood from three stages to four, adding a period called elderhood. In the chapters on adulthood, we address differences in lifestyle and life course that are attributable to historical events, medical advances, and cultural trends. Nevertheless, the increasing life expectancy, accompanied by a longer period of healthy later life and the elaboration of lifestyles, makes it difficult to chart a normative life course from early adulthood into elderhood (Aldwin & Gilmer, 2013).

In this book, you will also read about the important developmental issues of the prenatal period—a stage that Erikson's theory does not consider, but one that clearly plays a central role in setting the stage for a lifetime of vulnerabilities and competencies. These expansions of the stages of development demonstrate the natural evolution of a theoretical framework.

Finally, psychosocial theory and related research have been criticized as being dominated by a male, Eurocentric, individualistic perspective that emphasizes the ability to originate plans and take action, called **agency**, over the commitment to and consideration for the well-being of others, called **communion** (Abele & Wojciszke, 2007). Critics have argued that the themes of autonomy, initiative, industry, and personal identity, which reflect individuality, have been equated with psychological maturity. They suggest that relatively little attention has been given to the development of interpersonal connection and social relatedness. These latter themes have been identified as central for an

Courtesy of Philip and Barbara Newman

The positive relationships established between parents and their children are passed along from one generation to the next, fostering strong feelings of affection and care.

understanding of the psychosocial maturity of girls and young women. These themes also emerge in the study of collectively oriented ethnic groups, as discussed in chapter 2, cultures in which maturity is equated with one's ability to support and sustain the success of the family or the extended family group rather than with one's own achievement of status, wealth, or recognition (Boykin, 1994; Josselson, Lieblich, & McAdams, 2007).

Within the framework of psychosocial theory, the theme of connection is addressed directly through the first psychosocial crisis of trust versus mistrust in infancy. Then the thread is lost until early adolescence and early and middle adulthood, when group identity, intimacy, and generativity direct the focus back to the critical links that individuals build with others. The concept of the radius of significant relationships serves to maintain the perspective of the person interwoven in a tapestry of relationships, focusing especially on family and friends in childhood; the family, peer group, love relationships, and close friends in early and later adolescence; and on intimate partners, family, friends, and coworkers in adult life. A basic premise of psychosocial theory is that the self-concept is taking shape in constant interaction with the community (Schlein, 1987, 2007).

To extend the theme of connection, this book elaborates on developing capabilities for social interaction and differences in socialization practices and outcomes for men and women in our society. A variety of social abilities, including empathy, prosocial behavior, interaction skills, and components of social cognition, are traced as they emerge in the context of family relationships, friendships, peer groups, and work. This book considers ethnic groups as well as broader social influences on development and the importance of a collective orientation toward responsibility in caring for children and creating a sense of community.

FURTHER REFLECTION *Analyze how well psychosocial theory meets the criteria for a scientific theory that were presented in chapter 2.*

A Recap of Psychosocial Theory

FIGURE 3.5 ▶ shows development as a building process that incorporates the six constructs of psychosocial theory. The structure grows larger as the radius of significant relationships expands and as the achievements of earlier stages are integrated into the behavior of the next stage of development.

How can you tell when a stage change has occurred? The resolution of the psychosocial crisis of a previous stage provides the ego strengths and skill acquisition needed to face the challenges and expectations of the next stage. Once a person is fully engaged in all the tasks of a new period of life, a new stage of life has begun. The person's energy, motivation, and concerns about self and others are directed toward new goals, and the expectations others have for the person's level of functioning shift. Just as we no longer applaud the 4-year-old for the ability to crawl, we no longer applaud the 30-year-old for the ability to hold a steady job. Evidence of a stage change can be marked by new preoccupations and plans, new worries, and a new approach to building and maintaining relationships. A wonderful aspect of human development is the continuing redirection of energy to new ambitions, building upon the satisfactions of prior achievements.

At the beginning of chapter 2, we introduced three questions one must ask in order to understand a theory. Let us now answer these questions with respect to psychosocial theory.

Which phenomena is the theory trying to explain? Psychosocial theory attempts to explain human development across the life span—especially patterned changes in self-concept development that are reflected in self-understanding, identity formation, social relationships, and worldview.

What assumptions does the theory make? Human development is a product of three interacting factors: biological maturation, the interaction between individuals and

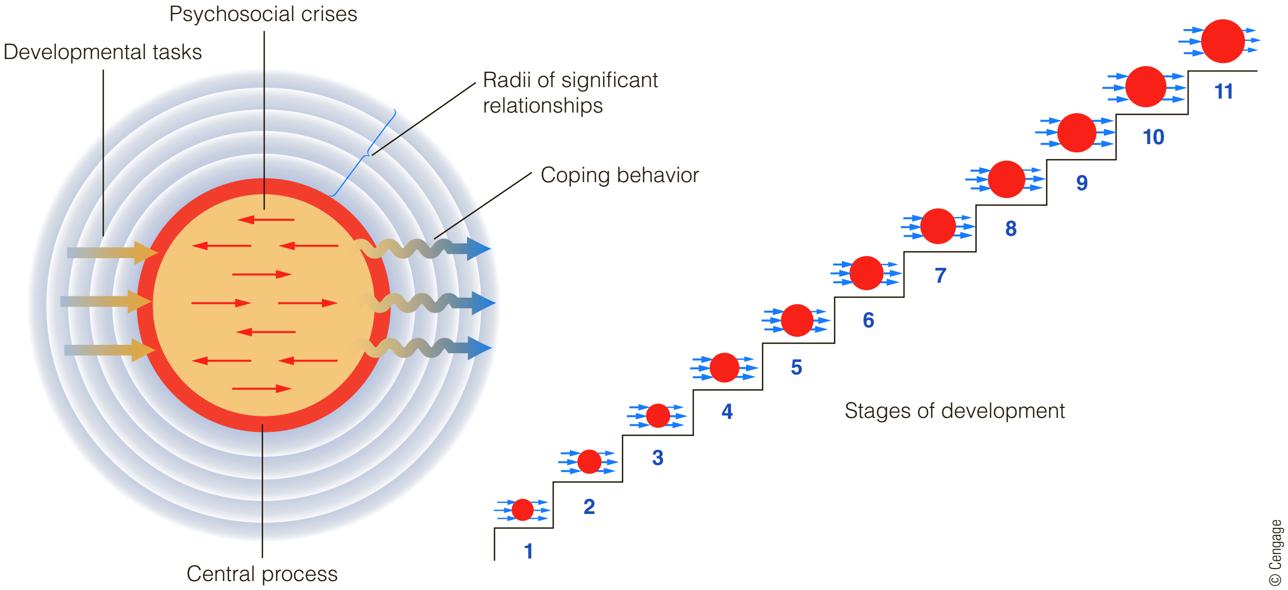

FIGURE 3.5 ▶ THE SIX BASIC CONCEPTS OF PSYCHOSOCIAL THEORY

Source: © Cengage

social groups, and the contributions that individuals make to their own psychological growth.

The theory makes the following six assumptions:

1. Growth occurs at every period of life, from conception through elderhood.
2. Individual lives show continuity and change as they progress through time.
3. In order to understand behavior, one must consider the integration of cognitive, physical, social, and emotional competencies, since these domains influence one another.
4. Every person's behavior must be analyzed in the context of relevant settings and personal relationships.
5. People contribute actively to their own development.
6. Diversity is a product of the interaction of the biological, the psychological, and the societal systems.

What does the theory predict?

1. There are 11 stages of development, which emerge in an ordered sequence. Issues of later stages can be previewed at an earlier time, but each issue has its period of ascendance. It takes the entire life span, from the prenatal period through elderhood, for all aspects of the person's potential to be realized.
2. Developmental tasks are dictated by the interaction of the biological, psychological, and societal systems during each stage.
3. A normal crisis arises at each stage of development, and a central process operates to resolve this crisis. The resolution of the crisis at each stage determines one's coping resources, with a positive resolution contributing to ego strengths and a negative resolution contributing to core pathologies.
4. Each person is part of an expanding network of significant relationships that convey society's expectations and demands. These relationships also provide encouragement in the face of challenges.

FIGURE 3.6 ▶ THE MECHANISM FOR POSITIVE AND NEGATIVE PSYCHOSOCIAL DEVELOPMENT

5. Development will be optimal if a person can create new behaviors and relationships as a result of skill acquisition and successful crisis resolution during each stage of growth. Lack of development and core pathologies result from tendencies that restrict behavior (especially social behavior) in general and new behavior in particular. The mechanisms for positive and negative development are diagrammed in FIGURE 3.6 ▶.

CHAPTER SUMMARY

OBJECTIVE 1 Explain the rationale for using psychosocial theory as an organizing framework for the study of human development.

Psychosocial theory offers a life-span view in which development is a product of the interactions between individuals and their social environments. The needs and goals of both the individual and society must be considered in conceptualizing human development. Predictability is found in the sequence of psychosocial stages, the central process involved in the resolution of the psychosocial crisis at each stage, and the radius of significant relationships. Individuality is expressed in the achievement of the developmental tasks, the balance of the positive and negative poles of each psychosocial crisis and the resulting worldview, and the style and resources for coping that a person brings to each new life challenge.

Connectivity is achieved in the way the person learns to relate in a radius of significant others who make demands, convey social expectations, and offer social rewards. Over time, the person becomes engaged in increasingly complex social groups and institutions. A person's worldview at a particular age is a product of past identifications and the resolution of previous psychosocial crises, contemporary pressures and opportunities, and hopes for the future. In our society, there is great diversity in the outcomes of this psychosocial process and in the transmission of social expectations from one generation of adults to the next generation of children.

OBJECTIVE 2 Define the six basic concepts of psychosocial theory.

Psychosocial theory accounts for systematic change over the life span through six basic concepts: (1) stages of development, (2) developmental tasks, (3) psychosocial crises, (4) a central process for resolving the crisis at each stage, (5) a radiating network of significant relationships, and (6) coping—the new behavior people generate to meet new challenges.

The basic concepts of psychosocial theory provide the framework for analyzing development across 11 life stages from the prenatal period through elderhood. Development is viewed as a building process that incorporates the six constructs of psychosocial theory. The structure grows larger as the radius of significant relationships expands, and coping strategies become more varied and complex as the developmental tasks of each stage are mastered and become available to face the challenges and psychosocial crisis of the next stage of life.

OBJECTIVE 3 Evaluate psychosocial theory, pointing out its strengths and weaknesses.

Psychosocial theory provides a broad, integrative context within which to study life-span development. The strengths and weaknesses of the theory are summarized in Table 3.6. The theory provides insights into the direction of development over the life span, highlighting human strengths and vulnerabilities and predictable shifts in worldview and self-understanding at each stage. The theory offers a framework for considering the ongoing interaction of individuals and their societies, pointing to the interconnections of people at various stages of life. The theory has been criticized for its lack of clarity about the mechanisms that explain change from one stage to the next. The psychosocial crises have been criticized as overemphasizing values of individuality as compared to values of connection and interdependence.

AS YOU READ ON . . .

Each chapter of this text, from chapter 4 through 14, is devoted to one life stage. Chapter 15 covers topics related to death and bereavement across the life span. With the exception of chapter 4, on pregnancy and prenatal development, each life-stage chapter starts with a discussion of the developmental tasks of that life stage. By tracing developments in physical growth, emotional growth, intellectual skills, social relationships, and self-understanding, you can recognize the interrelationships among all of these dimensions during each period of life.

In the second section of each chapter, the psychosocial crisis of that life stage is described, accounting for the tension by examining the individual's needs and personal resources in light of the dominant societal expectations. In addition to defining the crisis, we conceptualize the central process by which it is resolved. The resolution of the crisis at each stage is tied to new ego strengths and new core pathologies.

At the end of each chapter, we draw on the material we have discussed to analyze a topic that is of persistent concern to our society. These topics are controversial, and they may generate sentiment as they deepen understanding. We intend these sections to stimulate the application of developmental principles to real-world concerns.

CASEBOOK

For additional case material related to this chapter, see the case of "Ayesha and the Dinosaurs," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry Meyer, and Brenda J. Lohman, page 100. This case of an engaging 10-year-old illustrates ways in which the psychosocial strengths of trust, autonomy, initiative, and industry come together to support effective problem solving. The case provides an opportunity to discuss the usefulness of the central concepts of psychosocial theory for guiding understanding about positive development.

The period of pregnancy and prenatal development involves ongoing interactions between the fetus and the pregnant woman. Fetal development is guided by genetic factors in the context of the mother's health, social support, emotional well-being, and culture.

LEARNING OBJECTIVES

1. Summarize the process through which genetic information is transmitted from one generation to the next.
2. Differentiate the contributions of genetic factors to individuality through their role in controlling the rate of development, their influences on individual traits, and the genetic sources of abnormalities.
3. Trace the process of prenatal development from fertilization through three trimesters of pregnancy, including an understanding of infertility, alternative means of reproduction, and related ethical considerations.
4. Describe the birth process and analyze factors that contribute to infant mortality.
5. Analyze ways that the pregnant woman and the developing fetus influence each other, focusing on how pregnancy affects a childbearing woman and expectant father, and the impact of environmental influences on fetal growth, such as a woman's age, drug use, nutrition, environmental toxins, and stress.
6. Examine the impact of culture on pregnancy and childbirth.
7. Apply the psychosocial perspective to the topic of abortion, including the legal context, its social and emotional impact on women, and men's views.

Chapter Summary

— CASE STUDY Experiencing Pregnancy —

The experiences of pregnancy and childbirth provide a wonderful example of the interconnections of the biological, the psychological, and the societal systems. The following interview takes place when Katherine is in her eighth month of pregnancy. Katherine is married and has two children.

Interviewer: How have you been doing?

Katherine: Fine! Last month, I was nauseous and tired, but now I feel good.

Interviewer: Did you plan to have the baby?

Katherine: No.

Interviewer: How did it happen?

Katherine: We jokingly say it was an immaculate conception. I was using a diaphragm, but since I'm regular, I didn't use it the first few days after my period and the doctors said that can happen.

Interviewer: How did you feel when it happened?

Katherine: I was basically happy, and then scared—mainly shocked, I felt, "Me! How could it happen?" The other two were so carefully planned. Of course, unconsciously maybe I wanted it.

Interviewer: What has it felt like being pregnant?

Katherine: I haven't had the euphoria that I had with the first one, when everyone treats you special, and you feel so good. Because now, I'm mainly with mothers and they do it all and it's not so special to be pregnant. I feel heavy and fat.

Interviewer: How will you feel when you're no longer pregnant?

Katherine: I'll probably still feel heavy and fat! (laughs)

Interviewer: Will you miss being pregnant at all?

Katherine: With my other two, I didn't miss being pregnant, but I did miss it when I stopped nursing. I felt very sad then. There are times when I just lie there and love the feel of the baby inside me, but I don't relish being pregnant.

CASE ANALYSIS Using What You Know

1. Describe the interactions among the biological, the psychological, and the societal systems as they relate to Katherine's experience of pregnancy.
2. Speculate about the impact of this unplanned pregnancy on other members of the family, including Katherine's husband and her two children.
3. Think about being pregnant. List some of the positive and negative aspects of this life experience.
4. How might Katherine have been better educated about the risks associated with not using her diaphragm in the first few days of her menstrual cycle? Evaluate the current quality of family planning information for most U.S. couples. Where do they receive this information? How well is it understood?

When does an individual's life story begin? At birth? At conception? At the births of one's parents or one's grandparents? We are each linked back in time, through a lifeline comprising our ancestry, culture, and genetic makeup. This chapter begins the story of development at the molecular level of genes and chromosomes, moves to the physical maturation of the fetus during the prenatal period, and then expands the view of early development by considering the psychosocial, interpersonal, and cultural contexts of the period of pregnancy.

Genetic factors guide the tempo of growth and the emergence of individual characteristics. As the human fetus grows, sensory and motor competencies emerge. The psychosocial environment provides both resources for and challenges to healthy development. Cultural attitudes toward pregnancy and childbirth, poverty and the associated stressors, support from the child's father and other significant family members, maternal nutrition, and exposure to toxins or drugs are among the factors that affect fetal growth.

The chapter ends with the Applied Topic Abortion. As you read about the contributions of genetic factors to development, the process of fertilization, normal fetal development, and the psychosocial and cultural contexts of pregnancy and childbirth, you will gain a more complex, nuanced understanding of this topic and the controversies that surround it. ●

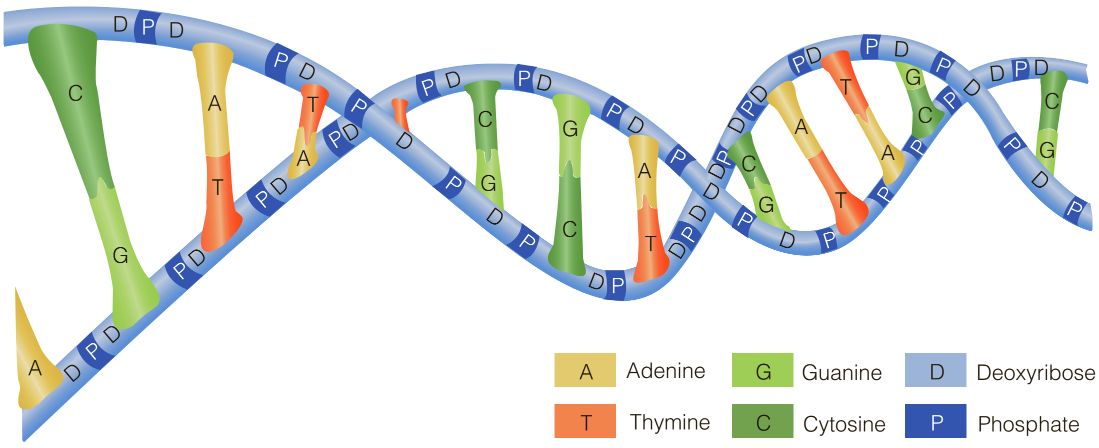
Genetics and Development

OBJECTIVE 1 Summarize the process through which genetic information is transmitted from one generation to the next.

Variability, which is so essential for human survival, is guaranteed, in part, by the complexity of the human *genome* (all the genetic material in the chromosomes of a human being) and the mechanisms for genetic inheritance. In this section, we briefly review the biology of genetics and the laws that govern the transmission of genetic information from one generation to the next. As parents, teachers, and human service professionals, we are encouraged to value and respond to human diversity. The growing knowledge about human genetics provides a foundation for appreciating the biological basis of this diversity. An excellent source of information and links about the history, results, ethics, and future applications of the Human Genome Project can be found on the Human Genome Project website sponsored by the U.S. Department of Energy at genomics.energy.gov.

Chromosomes and Genes as Sources of Genetic Information

Genetic information links each new person to the human species in general and also to a specific genetic ancestry. The term "inherited characteristics" refers to two different kinds of heredity. The first includes all the genetic information that comes to us



© Cengage

FIGURE 4.1 ▶ DIAGRAM OF A SMALL PART OF A DNA MOLECULE The biochemical basis of genetic information is the DNA (deoxyribonucleic acid) molecule, which has the shape of a double helix (i.e., it looks somewhat like a twisted rope ladder). The sides of this ladder comprise alternating units of sugar (deoxyribose) and phosphate, and its rungs are made up of pairs of nitrogen bases (so named because they contain the element nitrogen as well as hydrogen and carbon). The four nitrogen bases involved are adenine (A), guanine (G), cytosine (C), and thymine (T). They are often referred to by their initial letters A, G, C, and T and are called the genetic alphabet.

as members of the human species. Most inherited genetic information is shared by *all* human beings, such as patterns of motor behavior (e.g., walking upright), brain size, and body structure, including the proportional size of the head, torso, and limbs. Two of the most relevant of these species-related characteristics are the readiness to learn and the ability to participate in social interactions. The second kind of heredity consists of characteristics that have been transmitted through a specific *ancestry*. Hair color, skin color, blood group, and height result from the genetic information passed on from one generation to the next.

Chromosomes, the long, thin strands of genetic material located in the cell nucleus, are formed from chains of DNA molecules (see FIGURE 4.1 ▶). Most single **genes** are composed of a piece of DNA that codes for the production of one protein and occupies a specific place on a chromosome. An estimate based on **genome** mapping places the number of these genes at about 20,500, which is less than 10 percent of the entire genome (Powledge, 2014; Rands, Meader, Ponting, & Lunter, 2014). In addition to the functional regions that specify the code for making proteins, some sequences of DNA have a regulatory function. They control or modify the activity of the nearby genes and contribute to basic processes that allow copies of DNA to be replicated during cell division. Recent technologies and studies of the genome have revealed that there are many variations in the structure of the genomes among healthy individuals. These variations include insertions, deletions, rearrangements, and differences in the location of gene sequences. The consequence of these variations for normal development and disease are not entirely known (Zhang et al., 2013).

The important work of the genes is to produce proteins, which then guide cellular formation and functioning. Proteins, which are large, complex molecules comprised of amino acids, perform most life functions and make up the majority of cellular structures. The group of all proteins in a cell is called its **proteome**. "Unlike the relatively unchanging genome, the dynamic proteome changes from minute to minute in response to tens of thousands of intra- and extracellular environmental signals. A protein's chemistry and behavior are specified by the gene sequence and by the number and identities of other proteins made in the same cell at the same time and with which it associates and reacts" (U.S. Department of Energy, 2003). Therefore, at the cellular level, genetic and environmental sources of information are continuously interacting to influence the functions of the cells.

In each chromosome pair, one chromosome comes from the father and one from the mother. The chromosome pairs differ in size. In 22 pairs of chromosomes, both members are similar in shape and size. They also contain the same kinds of genes. The 23rd pair of chromosomes is a different story: Female humans have two X chromosomes, and male humans have one X and one Y chromosome. The X and Y notation is used because these chromosomes differ in shape and size (the X chromosome is longer than the Y chromosome). There are very few similarities in the genes present on the X and Y chromosomes.

One common misconception is that there is one gene for each specific trait such as sociability, intelligence, or criminality. Single genes do not determine most human behaviors. Only certain rare disorders such as Huntington's disease have a simple mode of transmission in which a specific mutation confers the certainty of developing the disorder. Most types of behavior have no such clear-cut pattern and depend on interplay between environmental factors and multiple genes (McGuffin, Riley, & Plomin, 2001).

The Principles of Heredity

Certain basic ideas about the process by which information is transmitted from parent to offspring were discovered by Gregor Mendel (1866), a monk who studied the inherited characteristics of plants, particularly garden peas. Mendel chose the garden pea plant as his focus of study because he was able to follow two generations of plants in a single growing season. Today most studies of genetics use the fruit fly, which reproduces every two weeks,

Monkey Business Images/Shutterstock.com

Family resemblance is influenced by the transmission of genes that guide the production of melanin, which can be detected in similarity of hair color, eye color, and skin tones.

or certain bacteria that reproduce every 3 to 5 hours. Imagine the patience and care that were needed for Mendel to follow the path of certain characteristics over multiple generations of plants. In his work, he observed plants that had readily distinguishable traits, like the color of the flowers they produced or the color of their seeds. From his experiments, in which he combined plants with certain features in systematic ways, he was able to deduce the basic principles of how information is passed along from one generation to the next. These principles, which were gathered from the research on garden peas, also apply to humans.

1. The inheritance of specific traits occurs as units of information (now called genes) are passed from the parent generation to the child.
2. A person has two units of information about each trait. The person inherits one unit related to each trait from each parent (these are referred to as alleles).
3. A trait that was present in the parent may not show up in the child, but it is still present and can be passed along to the next generation.
4. In the process of reproduction, only one of the parent's alleles for each trait is passed along to the offspring. (We now know that this happens in the formation of the sex cells, which carry only one of each chromosome pair.)
5. Alleles for different traits are passed along independently. The information regarding eye color is not passed along with the information about blood type. (We now know that genes related to different characteristics are found on different chromosomes.)

As the study of genetics and the principles of heredity has progressed, our understanding of the dynamic nature of genes and the factors that can influence their expression has advanced. However, many of these basic ideas are still fundamental to our appreciation of the process through which genetic information is passed from one generation to the next.

Alleles

In the 22 pairs of identical chromosomes, each gene has at least two possible states or conditions, one on each chromosome in the pair. These alternative states are called **alleles**. Whatever the allelic state of the gene from one parent, the other parent's allele for that gene may be either the same or different. If both alleles are the same, the gene is said to be **homozygous**. If the alleles are different, the gene is **heterozygous**.

Genotype and Phenotype

The genetic information about a trait is called the **genotype** (e.g., the genetic information that encodes skin color). The observed characteristic (e.g., one's actual skin color) is called the **phenotype.** The phenotype is a result of the genotype and development in the environment. Genotype can influence phenotype in three different ways. First, the differences in the allelic states of several genes sometimes result in a **cumulative relation**, in which more than one pair of alleles influences the trait. An example of this kind of relation is the genetic contribution to height. The genotype for height is based on a number of genes. A person whose alleles of different genes are mostly for tallness will be tall; a person who receives many alleles of different genes for shortness will be short. Most people receive a mix of alleles for both tallness and shortness and are of average height.

Second, the differences between alleles may result in **codominance**, in which both genes are expressed in the new cell. An example of codominance is the AB blood type that results from the joining of an A blood type allele from one parent and a B blood type allele from the other parent. This blood type is not a mixture of A and B, nor is A subordinate to B or B to A; instead, a distinct blood type, AB, is formed.

Third, differences in the allele states of a gene may result in a **dominance** relation. Dominance means that if one allele is present, its characteristic is predominantly observed whether the other allele of the pair is the same or not. The allele that dominates is called the *dominant* allele. The other allele that is present, but whose characteristic is masked by the dominant allele, is called the *recessive* allele. Eye color is the result of a dominance relation. The allele for brown eyes (B) is dominant over the allele for blue eyes (b). The probability that the recessive trait of blue eyes will emerge in the offspring of two heterozygous parents is illustrated in FIGURE 4.2 ▶. The possible combinations of the gene related to brown or blue eye color are BB, Bb, bB, and bb. Only one combination, bb, which will occur on the average in only 25 percent of the offspring, results in a child with blue eyes. The other three genotypes result in one phenotype—brown eyes.

Epigenetics

Adding to the complexity of the laws of heredity are the processes of **epigenetics**. Epigenetics is the study of mechanisms that turn genes on and off. These are changes in gene expression that can be

FIGURE 4.3 ▶ EPIGENETIC MECHANISMS Environmental conditions such as a rich diet following a period of starvation can alter gene expression. These changes can turn genes on or off and may affect what gets passed down to succeeding generations.

Source: "From Epigenetics: UnfinishedSymphony," by J. Qiu, 2006, Nature, 441, no. 7090, pp. 143–145.

transmitted from one generation to the next but do not alter the genome itself. In other words, these processes influence the phenotype (gene expression) but not the genotype. You will recall that in psychosocial theory, the epigenetic principle refers to a biological plan for growth that allows each function to emerge systematically until the fully functioning organism has developed. In the early 1940s, this term was used to consider the role of genetics in guiding development. Here, the same term is used to consider the ways that the environment can modify gene expression.

Two epigenetic processes are imprinting and epigenetic marks. **Imprinting** is a condition in which genes from either the mother or the father are silenced. For most genes, we inherit two working copies, one from mother and one from father. However, for imprinted genes, only one working copy is inherited; the other is silenced by the presence of a chemical tag that sits along the gene (Genetics Science Learning Center, 2014; Kelsey & Bartolomei, 2012). Under conditions of imprinting, the genes from both parents are present on the DNA strands and are copied by the RNA, but only the genes from one parent are used in making proteins. As a result, even though there are two alleles in the genotype, only the mother's or the father's allele is expressed in the phenotype. There is an assumed adaptive advantage to having some genetic information silenced selectively depending on its origin from the paternal or maternal genetic source, but the mechanisms that might explain or account for this advantage are not yet clear. Many developmental disorders and diseases are linked to imprinted genes. For example, in a certain gene related to growth, the father's allele is expressed and the mother's allele is silenced. If for some reason the imprinting is disrupted and both alleles are expressed, the cell is likely to become cancerous. Future study of imprinted genes is expected to contribute significantly to our understanding of the genetic and epigenetic basis of disease (Jirtle & Weidman, 2007).

Epigenetic marks are chemicals that sit on top of the genes and instruct them to switch on or off (FIGURE 4.3 ▶). These marks can be influenced by environmental factors such as overabundant eating, smoking cigarettes at an early age, taking particular vitamins during the prenatal period, or exposure to extremely stressful conditions. When the epigenetic marks are altered, the impact is seen in subsequent generations. For example, researchers studied the long-term impact of famine and feast in a small Swedish community. They found that the children and grandchildren of those children who had experienced periods of near starvation followed by a year of overeating had substantially shorter lives than the offspring of those who experienced only the famine, but no overeating. In contrast to the slow process of genetic modification through natural selection, epigenetic studies show how exposure to critical environmental factors at key periods of life can predispose one's children and grandchildren to genetically based vulnerabilities. These environmental influences are distinct from the prenatal exposure of the fetus to malnutrition or toxins, discussed later in this chapter, which may result in developmental delay or disruption. Epigenetic studies link developmentally time-sensitive exposure to environmental conditions to the gene expression in one or more generations of offspring (Pembrey, 2008; Pembrey, Bygren et al., 2006).

The study of intergenerational inheritance due to epigenetic marks is still in its infancy. Research with animal models suggests that some of a grandparent's experiences with nurturing and/or harsh and neglectful parenting can be passed on to their children and grandchildren (Weaver, Cervoni et al., 2004). In the field of behavioral epigenetics, particular focus has been given to the impact of child abuse and exposure to traumatic life experiences that alter the brain chemistry. However, this research is still considered controversial because epigenetic marks are difficult to trace. They can form quickly. Moreover, given the sensitivity of epigenetic marks to environmental conditions, it is also possible that sensitivities that are passed from parent to offspring could be modified by exposure to different environments (Hurley, 2013; Genetic Science Learning Center, 2015a).

Sex-Linked Characteristics

Certain genetic characteristics are said to be **sex linked** because the gene for the specific characteristic is found on the sex chromosomes (X and Y). The female ova carry only X chromosomes. Half of the male sperm carry Y chromosomes, and half carry X chromosomes. Male children can be produced only when a sperm carrying a Y chromosome fertilizes an egg, and the result is an XY combination in the 23rd chromosome pair. All sperm carrying X chromosomes will produce female children.

Sex-linked traits are more likely to be observed in male offspring, even though they may be present in the genotype of female offspring. You will understand this more readily if you visualize the XY chromosome pair. When a trait is carried on the Y chromosome, it will be inherited and transmitted only by male offspring, because only male offspring have the Y chromosome. Interestingly, the Y chromosome is quite small, and few exclusively Y-linked traits have been identified. One of the few key genes that has been located on the Y chromosome is SRY, which is responsible for setting into motion the differentiation of the testes during embryonic development. Once the testes are formed, they begin to produce hormones that account for further differentiation of the male reproductive system.

Sex-linked traits that are carried on the X chromosome are more likely to be observed in male offspring than in female offspring, because male children do not have a second X chromosome to offset the effects of an X-linked trait. Hemophilia A, the most common type of hemophilia, is an example of such a sex-linked trait. Individuals with hemophilia lack a specific blood protein that causes blood to clot after receiving a wound (Medline Plus, 2014). The allele for hemophilia is a recessive trait carried on the X chromosome; however, it is most likely to affect men (see FIGURE 4.4 ▶). Half (50 percent) of the male offspring of female carriers have the disease, and 50 percent of their female offspring are carriers. All female children of a man with hemophilia are carriers of the trait. This disease affects approximately 1 in 5,000 men.

Other genes are expressed exclusively in one sex but are not found on the sex chromosomes per se. For example, the genes for male beard development and female breast development are not located on the sex chromosomes. However, these characteristics will emerge only in the presence of the appropriate hormonal environment, which is directed by the sex chromosomes.

Genetic Sources of Individual Differences

OBJECTIVE 2 Differentiate the contributions of genetic factors to individuality through their role in controlling the rate of development, their influences on individual traits, and the genetic sources of abnormalities.

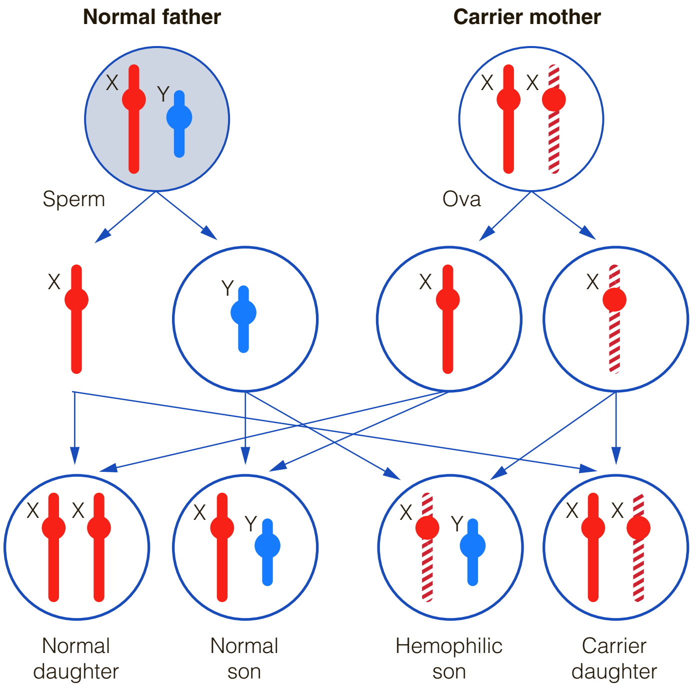

FIGURE 4.4 ▶ SEX-LINKED INHERITANCE OF HEMOPHILIA The allele for hemophilia is carried on the X chromosome. If the allele is either heterozygous or homozygous for the dominant trait (normal blood clotting), a female child will have normal blood-clotting capabilities. Only if she is homozygous for the recessive trait (a very rare occurrence) will she be hemophilic. A male child, on the other hand, has only one allele for the clotting gene, which he inherits from his mother. If that allele is dominant, his blood will clot normally, but if it is recessive, he will be hemophilic.

The study of genetics reveals that individual variability is due to the combination of the many variations in environments and experiences that confront a growing person and the variability built into the biological mechanisms of heredity. Each adult couple has the potential for producing a great variety of genetically distinct children. Four areas in which genetic factors contribute to individual variability are *mutations*, *rate and sequence of development*, *individual traits*, and *abnormal development*.

Mutations

Every time a cell divides its DNA is copied. A **mutation** refers to a natural process that changes some aspect of the DNA sequence; it is like a *typo* in the reproduction or copying process. These errors may be a result of a normal process of cell division. However, they may also result from exposure to radiation, chemicals, or infection by viruses. Cells have the ability to repair these errors. Unrepaired mutations that occur in body cells are not passed on to offspring. However, if a change goes unrepaired in an egg or sperm cell, it may be passed along to the next generation. This means that some aspects of the DNA of the offspring are a bit different from the DNA from either parent. In this way, mutations contribute to genetic variation, especially when they occur within genes, rather than in the large amount of DNA that falls between the genes.

Genetic mutations are a source of variation at the level of the allele. If the variation contributes to fitness and increases the probability of the offspring's survival, we could say it was a positive mutation. If the variation disrupts important protein development, causes disease or vulnerability, or prevents reproductive success, we could say it was a negative mutation. However, many mutations, like those that contribute to variations in skin color, blood type, or the shape of one's ears, are neither good nor bad. They are just sources of differences between individuals (Genetics Home Reference, 2015a; Genetics Science Learning Center, 2015b).

Genetic Determinants of the Rate and Sequence of Development

Genes regulate the rate and sequence of maturation. The concept of an epigenetic plan for growth and development is based on the assumption that a genetically guided system promotes or restricts the growth of cells over the life span. Genetic factors have been found to play a role in behavioral development, including the onset of various levels of reasoning, language, and social orientation (Moore, 2015; Plomin, DeFries, Knopik, & Neiderhiser, 2012).

Evidence for the role of genetics in guiding the rate and sequence of development comes largely from studies of identical twins (who have the same genotype). The rates at which identical twins develop are highly correlated. A number of characteristics—including the timing of the acquisition of motor skills, personality development, changes in intellectual capacity among aged twins, and the timing of physical maturation—show a strong genetic influence (Bouchard & Pederson, 1999; Segal, 2010; Segal & Johnson, 2009).

Genes can be viewed as internal regulators that set the pace for maturation. They signal the onset of significant developmental changes throughout life, such as growth spurts, the eruption of teeth, puberty, and menopause. They also appear to set the limits of the life span. A small number of genes influence how many times the cells of a specific organism can divide and replicate.

Differences in the rate of development contribute to our understanding of psychosocial growth. For example, you may encounter charts and websites that offer milestones about the age at which infants and young children are expected to perform various motor skills or language abilities. However, these and other capacities evidence considerable variability in the timing and rate of development. Differences in age at crawling or walking, for example, bring children into contact with new aspects of their environments and provide them with changing capacities for exploration at different chronological ages.

Genetic Determinants of Individual Traits

Genes contain specific information about a wide range of human characteristics, from eye color and height to the ability to taste a particular substance called phenylthiocarbamide (PTC) (which to tasters is bitter, but to nontasters has no taste at all). Have you ever wondered why some people are very picky eaters, and others will eat anything? One hypothesis has to do with difference in the PTC gene. Tasters seem to have more food aversions. This might come in handy if the food sources are spoiled or tainted, but it might be a disadvantage if there are limited food supplies.

Some characteristics are controlled by a single gene. However, most significant characteristics, such as height, weight, blood group, skin color, and intelligence, are guided by the combined action of several genes. When multiple genes are involved in the regulation of a trait, the possibilities for individual differences in that trait increase. Because many characteristics are regulated by multiple genes, the variety of human phenotypes is enormous.

Genetic factors also play a substantial role in individual differences in personality traits (Barondes, 2011; Borkenau, Riemann, Angleitner, & Spinath, 2001; Plomin & Spinath, 2004). Traits such as *sociability* (a tendency to be outgoing), *inhibition* (a tendency to be cautious and socially shy or withdrawn), and *neuroticism* (a tendency to be anxious and emotionally sensitive) are pervasive dimensions of personality that appear to have strong genetic components. Even in rather specific areas of personality, such as political attitudes, aesthetic preferences, and sense of humor, identical twins show greater similarity than fraternal twins. Research on the biological basis of sexual orientation suggests that genes influence the development of the part of the brain that guides sexual behavior. Identical twins are more likely to have the same sexual orientation than are fraternal twins or adoptive siblings (Bailey & Pillard, 1991, 1994; LeVay, 1991, 2011; Ngun & Vilain, 2014).

The notion that genetic factors influence personality and behavior has led to extensive research to identify specific genes responsible for particular traits such as cooperativeness, impulse regulation, or vulnerability to stress. In this search, an important perspective has emerged for understanding how genes and the environment interact. As discussed above, differing environmental conditions at a molecular, biological, or behavioral level can alter the expression of one or more genes through epigenetic marks, resulting in vulnerabilities or resilience. You have probably met people who seem to just "roll with the punches" whereas others seem to get ruffled by even minor disturbances. Genetic factors can influence whether individuals are more or less distressed by their environments (Belsky, 2011; Caspi, Hariri, Holmes, Uher, & Moffitt, 2010). What is more, people with the same genotype can demonstrate different phenotypes depending on their exposure to harsh or nurturing parenting (see Figure 4.5 ▶).

As people mature and become increasingly assertive in selecting certain experiences and rejecting others, their own temperaments, talents, intelligence, and level of sociability will guide the kinds of environments they select, strengthening certain genetic predispositions while dampening others. The more control a person has over decisions affecting lifestyle, work and leisure activities, and relationships, the greater impact certain innate or genetically guided preferences are likely to have on these decisions.

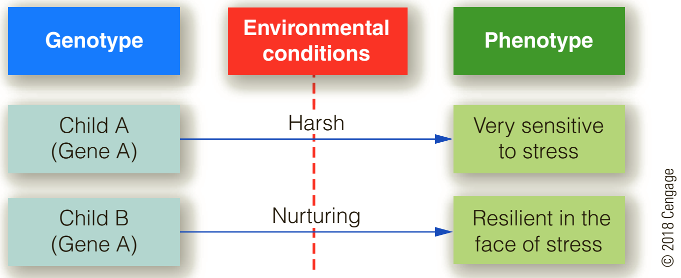

FIGURE 4.5 ▶ EXPRESSION OF SAME GENE IN DIFFERENT ENVIRONMENTS

Genetic Determinants of Abnormal Development

In addition to characteristics such as physical appearance, temperament, talent, and intellectual capacity, a wide variety of abnormalities, or *anomalies*, have a genetic cause. The most dramatic anomalies result in a spontaneous abortion of the fetus early in the pregnancy. Pregnancy loss that occurs on its own before 20 weeks of gestation is referred to as a **miscarriage**. Approximately 10 percent to 25 percent of diagnosed pregnancies end in miscarriage (American Pregnancy Association, 2015). The risk of miscarriage is lower for women under age 30, increases to 20 percent to 35 percent among women ages 35–45, and is as high as 50 percent among women age 45 and over (American Pregnancy Association, 2015). The majority of these early-term miscarriages are due to chromosomal abnormalities in the fertilized zygotes (the developing organism formed from the father's sperm and the mother's egg) that prevent normal fetal development.

Of those infants who survive the neonatal period, an estimated 3 percent to 5 percent have one or more major recognizable anomalies or birth defects (Cunningham et al., 2014). The incidence of anomalies increases to 6 percent to 7 percent as some disorders are diagnosed later in childhood. Some birth defects are linked to a specific chromosome or to a single gene. Other birth defects are linked solely to environmental factors, such as drugs, medications, and fetal and maternal infections. Most malformations, however, result from the interaction of genetic vulnerabilities and environmental hazards or are of unknown origin (Moore, Persaud, & Torchia, 2015). Some birth defects, such as respiratory distress associated with underdeveloped lungs, can be corrected through medical interventions. Others, such as injury of the small or large intestines, which disrupts digestion and creates a site for repeated infections, may remain a source of life-long illness and/or disability (Institute of Medicine, 2007).

Examples of genetic and **chromosomal disorders** are listed in Table 4.1. The disorders are presented in two broad

Table 4.1 **Examples of Genetic and Chromosomal Disorders**

Genetic Disorders
Autosomal dominant gene
Huntington's chorea: Rapid, jerky, involuntary movements; deterioration of muscle coordination and mental functioning. Symptoms usually do not appear until age 35–50. Caused by genetic defect on chromosome 4.
Marfan's syndrome: Elongated fingers; deformed chest and spine; abnormal heart. Tendons, ligaments, and joint capsules are weak.
Autosomal recessive gene
Albinism: Hair, skin, and eyes lack the pigment melanin. Often accompanied by visual problems and a susceptibility to skin cancer.
Cystic fibrosis: Certain glands do not function properly. The glands in the lining of the bronchial tubes produce excessive amounts of thick mucus, which leads to chronic lung infections. Failure of the pancreas to produce enzymes necessary for the breakdown of fats and their absorption from the intestines leads to malnutrition. Sweat glands are also affected. Often fatal by age 30. Caused by missing base pairs on chromosome 7.
Sickle-cell anemia: Malformation of red blood cells reduces the amount of oxygen they can carry. Results in fatigue, headaches, shortness breath on exertion, pallor, jaundice, pain, and damage to kidneys, lungs, intestine, and brain.
Tay-Sachs disease: Absence of a certain enzyme results in the buildup of harmful chemicals in the brain. Results in death before age 3.
X-linked recessive gene
Color blindness: Defect of light-sensitive pigment in one or more classes of cone cells in the retina of the eye or an abnormality in or reduced number of cone cells themselves. The two common types are reduced discrimination of light wavelengths within the middle (green) and long (red) parts of the visible spectrum.
Hemophilia: Absence of a blood protein (factor VIII) reduces effectiveness of blood clotting. Severity of disorder varies. Bleeding episodes likely to begin in toddlerhood.
Chromosomal Disorders
Autosomal abnormality
Down syndrome: Additional 21st chromosome; also called trisomy 21. The extra chromosome results in physical and intellectual abnormalities, including IQ in the range of 30–80; distinctive facial features, heart defects, intestinal problems, hearing defects; susceptibility to repeated ear infections. Tendency to develop narrowing of the arteries in adulthood, with attendant increase in risk of heart disease.
Sex-chromosome abnormalities
Turner syndrome: Usually caused by a lack of one X chromosome in a girl; sometimes one of two X chromosomes is defective; occasionally some base pairs are missing on an X chromosome. These abnormalities result in defective sexual development and infertility, short stature, absence or retarded development of secondary sex characteristics, absence of menstruation, narrowing of the aorta, and a degree of mental retardation.
Klinefelter syndrome: One or more extra X chromosomes in a boy. This abnormality results in defective sexual development, including enlarged breasts and small testes, infertility, and often mental retardation.

This table is derived from information available at the National Institute of Health website, Genetics Home Reference(2015b) http://www.genome.gov/10001204 categories: those associated with specific genes and those associated with chromosomal abnormalities. Within those categories, some disorders are found on 1 of the 22 pairs of autosomal chromosomes (chromosomes other than the sex chromosomes), and others are on one of the sex chromosomes. There are more than 1,100 genes for which at least one disease- related mutation or alternate allele has been identified using the map-based approach to gene discovery. However, many diseases are thought to involve multiple genes in some form of interaction. Moreover, many diseases that have an identified genetic basis—such as hypertension, schizophrenia, or coronary artery disease—are expressed in certain environments, including the prenatal environment, and not in others (Fox, Hane, & Pine, 2007; Peltonen & McKusick, 2001).

Certain genetic diseases are linked directly to our ancestry; therefore, their incidence is higher in certain populations than in others (National Institutes of Health, 2015a). For example, the incidence of Tay-Sachs disease is especially frequent in Jews who settled in Eastern Europe. One in every 27 Jews in the United States carries the gene. Thalassemia, a disease involving faulty production of hemoglobin (which carries oxygen in the blood), is found most often in people of Mediterranean, Middle Eastern, and Southeast Asian origins. The variety of genetic abnormalities serves to broaden the range of individual variability. Many of these irregularities pose a challenge both to the adaptive capacities of the affected person and to the caregiving capacities of the adults involved.

Robin Nelson/PhotoEdit

Larry has a family history of cystic fibrosis. He and Leila have come to talk with a genetic counselor to help them evaluate the likelihood that their children would have this condition, and how to deal with this situation.

Genetic Technology and Psychosocial Evolution

Psychosocial evolution has typically been differentiated from biological evolution in that change is accomplished by social mechanisms, such as parenting, education, and the media, rather than incorporated in the genetic structure. As a result of scientific knowledge, however, we are entering an era when it is possible to intervene to influence the genotype. One such intervention is **genetic counseling** (Medline Plus, 2015). Individuals and couples with a family history of a genetic disease—or who for some other reason worry about the possibility of transmitting a genetic disease to their children—can have blood tests to identify genes that may result in the inherited disorder. The locations of the genes that account for such abnormalities as Tay-Sachs disease, sickle-cell anemia, Duchenne muscular dystrophy, and cystic fibrosis have been identified. Couples who have reason to believe that they may carry genes for one of these diseases can be advised about the probability of having children who may be afflicted. If significant numbers of the carriers of genetic diseases decided not to reproduce, the incidence of these diseases in the population would decline over time. Thus, a psychosocial intervention would modify the gene pool.

Ethical Considerations

Gene transfer; the patenting of new life forms created through genetic engineering; genetic fingerprinting, which is used to help identify criminal suspects; and cloning from an adult mammal are some of the topics that are raising new ethical concerns. There is consensus that the use of gene therapy to try to treat serious diseases such as severe combined immunodeficiency (SCID) or cancer is ethical. This type of gene therapy targets body cells such as bone marrow or blood cells. However, there is less agreement about germline gene therapy in which genes are inserted into gametes to try to prevent or modify the characteristics of offspring. Germline gene therapy is intended to modify disease-causing-genes in order to prevent their expression in the offspring or reduce the risk of passing certain mutations from one generation to the next. You can read more about the ethical controversies surrounding germline gene therapy at yourgenome.org (YourGenome.org, 2015).

Even the advances in identifying genetic markers for specific diseases can lead to ethical dilemmas. Three sources of federal legislation address prevention of discrimination based on genetic information. The Genetic Information Nondiscrimination Act of 2008 and the 2000 Executive Order prohibit discrimination in federal employment based on genetic discrimination. The 2010 Affordable Care Act contains further anti-discrimination measures including prevention of health insurers from refusing individuals coverage because of pre-existing conditions, including genetic diseases, and prevention of adjustment of premiums because of medical conditions (U.S. Department of Energy, 2013). State laws addressing discrimination on the basis of genetic diseases or the requirement for genetic testing as a condition of employment are less consistent.

The possibility of reproducing genetically identical clones from human tissue has stirred the conscience of the religious, political, and medical communities. Is it ethical to clone human genes so that great scholars, scientists, and artists can walk the Earth again? Should cloning become an approved technology for coping with infertility?

The debate about cloning has extended to include human stem cell research. Stem cells are unspecialized cells that have the potential to develop into any type of organ in the body. In the 3- to 5-day-old human embryo, these stem cells become the basis for all the organs that emerge during gestation. In some adult tissues, including bone marrow, muscle, and lungs, stem cells can generate replacement for cells that have been lost through wear and tear, injury, or disease (NIH, 2015b). In the early work, stem cells were derived from human embryos that were not going to be used for reproductive purposes. Now, however, adult somatic cells can be genetically manipulated to return them to an "unprogrammed" state, allowing them to take on the same properties as embryonic stem cells. This approach avoids much of the ethical controversy about the use of embryonic stem cells, allowing the research in this field to expand (Brind' Amour, 2010; NIH, 2015b).

Gene X Environment Interactions and Behavior

Forget the idea of nature versus nurture. Genes cannot be expressed without an appropriate environment, including the biological environment at the cellular level and the physical and social environments at the larger systems levels. For a genotype to be fully expressed in the phenotype, many environmental supports must be in place. For example, a human being needs to breathe oxygen. If an infant is deprived of oxygen for a long time in the prenatal period or during the birth process, the genetic potential for intelligence will be compromised. As illustrated in the discussion of epigenetic marks, individuals and their environments are in a state of dynamic interaction and change, each modifying the other. As the study of the human genome continues, we are appreciating that there is significant individual variability in sensitivity to the environment and the possibility of changing sensitivities to the environment at various points in the life span.

Genetics and Intelligence

One area that has received considerable attention is the relative contributions of genetic and environmental factors to **intelligence**. To what extent is a person's intelligence set by hereditary factors? To what extent is it a product of experience? Intelligent behavior requires the successful integration of both. It relies on the structure of the central nervous system and the sense receptors, which are products of genetically guided information. However, the healthy functioning of these systems requires adequate nutrition, rest, and freedom from disease—conditions that vary with the environment. Intelligent behavior builds on experiences with diverse stimuli, social interactions, and schooling—all elements of the physical and social environment.

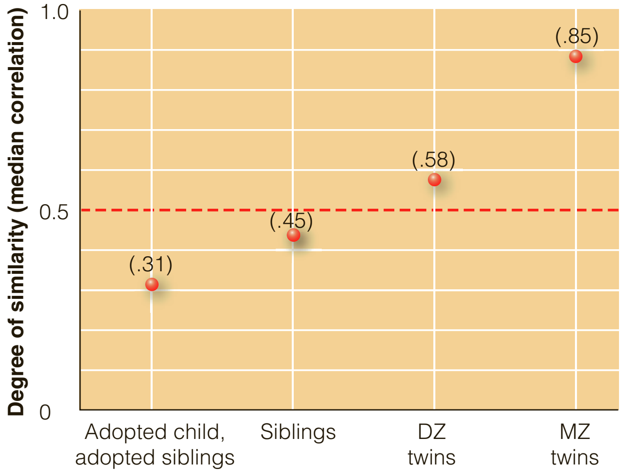

FIGURE 4.6 ▶ SIMILARITY IN INTELLIGENCE AMONG SIBLINGS AT FOUR LEVELS OF RELATIONSHIP

Source: From "Familial Studies of Intelligence: A Review," by T. J. Bouchard and M. McGue, 1981, Science, 212, pp.1055–1059.

The influence of genetic factors on intelligence may be observed in three ways. First, specific genetic anomalies, such as Down syndrome, are known to disrupt the development of the central nervous system and interfere with cognitive functioning. Second, the contributions of genetics to intelligence are observed through the study of family relationships. Family members may be related closely or distantly. The closer the biological relationship, the more similar the genetic makeup. If intelligence is influenced by genetics, close relatives should be more similar in intelligence than distant relatives. FIGURE 4.6 ▶ shows the degree of similarity found in more than 100 studies of intelligence in siblings at four different degrees of relationship (Bouchard & McGue, 1981). Similarity in intelligence increases with the degree of genetic relatedness. The correlation between pairs of monozygotic (identical) twins is 0.85, providing striking evidence of the contribution of genetics to intelligence. Fraternal, dizygotic (DZ) twins who share the same prenatal environment, home, and childrearing environments show much less similarity than do MZ twins and not much more than non-twin siblings. Third, recent research using Genome-wide Complex Trait Analysis (GCTA) in large samples allows for the quantitative analysis of genotypes and their relationship to measured intelligence (Plomin & Deary, 2015).

An overview of studies that have attempted to evaluate the contribution of genetic factors to cognitive ability suggests that genetics accounts for 50 percent of the variance, shared environmental factors for 33 percent of the variance, unshared environmental factors for 17 percent of the variance, and measurement error for 10 percent of the variance in intelligence (Gottesman, 1997). One might expect that genetic factors would play a smaller role in measured intelligence with age. However, the data suggest the opposite. The role of genetic factors associated with the inheritance of intelligence increases with age (Plomin & Deary, 2015; Plomin & Spinath, 2004). In other words, identical twins are more alike in intelligence in their adulthood and elderhood than they were as infants and young children.

The fact that intelligence is strongly influenced by genetic factors does not imply that environments have no impact or that intelligence is fixed or unchangeable. Through the field of cognitive neuroscience, we are learning more about the role of genes in the structure and functions of the brain and the ways that various genes

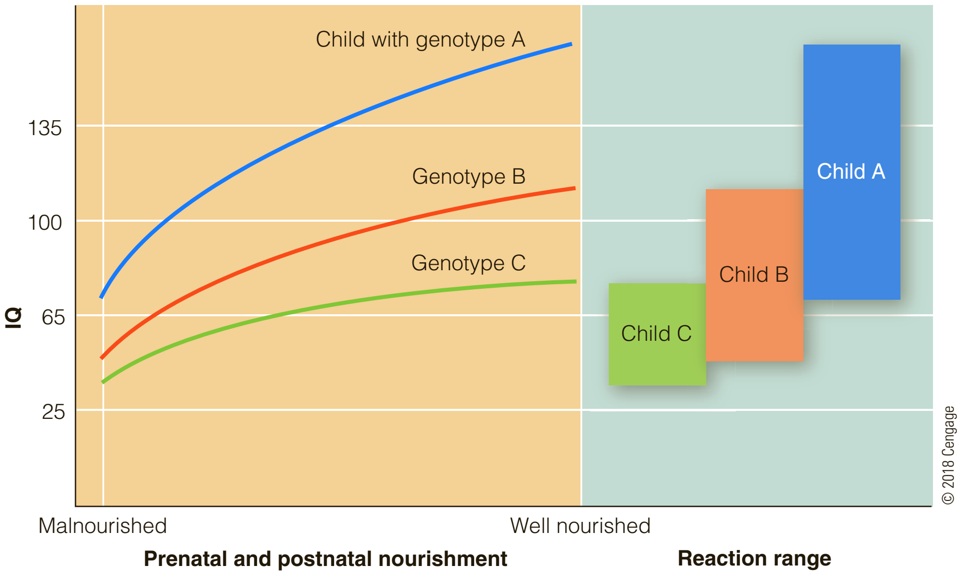

FIGURE 4.7 ▶ PLASTICITY OF INTELLIGENCE UNDER VARYING NUTRITIONAL ENVIRONMENTAL CONDITIONS

are related to cognitive capacities. As we will discuss later in the chapter, both the prenatal and postnatal environments have potential impact on the developing nervous system. Access to adequate nutrition, exposure to toxins, and birth trauma can all alter the phenotype with regard to intelligence. Moreover, tested IQ is only one way of conceptualizing intelligence, a concept that is widely debated in the social sciences. The question of how to think about and study the relationship of genetics and intelligence is moving into new and exciting areas of investigation (Plomin, 2004).

The Norm of Reaction

One way to think about the influence of genetics on behavior is to view the phenotype or observed behavior as a **norm of reaction**—that is, a pattern of possible phenotypes that are likely to be observed under different environmental conditions. This way of thinking about development highlights the importance of the concept of plasticity. **Plasticity** can be conceptualized as the degree of flexibility or variation that can be expressed at the level of an organ, a capacity, or a broad, developmental trajectory. Consider the example of handedness. If you are left- handed, and you break your left hand, you can learn to feed yourself with your right hand. It's not as smooth, but it's possible. So handedness, which is genetically influenced, is also plastic. And some people are more readily able to switch from one hand to the other than others; we call them ambidextrous.

Some characteristics of personality, intelligence, and emotional response are more plastic than others; that is, they are more sensitive to environmental stimulation or the conditions of childrearing than others. For example, whereas some children are very highly attuned to the social messages and childrearing practices of their parents, others are more resistant to parenting strategies and seem to grow up in tune with their own inner plan (Belsky & Pluess, 2009). Plasticity suggests that specific characteristics can be modified under various environmental conditions, and that some individuals are more responsive to the impact of the environment (for better or worse) than others.

FIGURE 4.7 ▶ shows the possible ranges of intelligence for three children under different nutritional conditions. Child A has greater genetic potential for intelligence than Child B, who has greater potential than Child C. Imagine a continuum of prenatal nutrition from very inadequate food resources to a very adequate diet. Some women living in very poor countries where there is widespread famine may have little to eat while they are pregnant. For other women, food supplies are plentiful. Now, imagine that after the child's birth, there is also a continuum of access to food. Some babies who were malnourished in the prenatal period continue to be malnourished in the early months of infancy. Other babies who were malnourished in the prenatal period begin to have access to an adequate diet after birth. And still other babies never experience food deprivation. Figure 4.7 provides a way of thinking about how levels of malnutrition may interact with the genotype for intelligence to produce different phenotypes.

When all three children are in food-deprived environments both prenatally and after birth, their IQs develop at the lower end of their potential range and the differences among the three phenotypes are reduced. When all three children are in environments where nutritional resources are plentiful both before and after birth, their IQs develop toward the upper end of their potential range and the differences among the three phenotypes are accentuated. Each child's intellectual ability can be expressed as a range of probable levels that are likely given the child's genetic potential and the quality of the nutritional environment. The more plastic a characteristic, such as intelligence, the more the phenotype will reflect environmental variation. The more channeled or constrained the characteristic, such as the shape of one's eyes or the length of one's fingers, the less environmental factors will influence the expression of the genotype in the phenotype.

Some genotypes flourish under certain conditions but not others. For example, consider the genotype for behavioral inhibition (Fox, Hane, & Pine, 2007). Behaviorally inhibited children are likely to stop their activity and seek proximity to their caregiver when faced with novel stimuli. Whereas some children have a genotype for intense inhibition, others have a genotype for low levels of inhibition. They are more active, outgoing, and exploratory and less disrupted or distressed by novelty. Now consider cultural differences that might interact with these predispositions for high or low inhibition. In cultures where children are expected to learn through observation and imitation, and where close physical contact between caregivers and mothers is the norm, one might expect the behaviorally inhibited children to be viewed as more normal and to thrive. The outgoing, exploratory, uninhibited children may be perceived as difficult, disruptive, and may experience more efforts on the part of caregivers to control or constrain their behavior. Children with a genotype that predisposes them to be outgoing and active might experience high levels of distress and self-doubt in this type of environment. In other cultures, where the norm is toward early independence and encouragement for exploratory behavior, the inhibited infants will require especially sensitive and supportive caregiving in order to thrive. Some parents may add to their inhibited infant's distress by rejecting these infants or conveying impatience with their infant's sensitivity, perceived clinginess, and avoidant behavior.

John Henley/Corbis/Getty Images

Even though children with Down syndrome have mild to moderate disabilities, they also have many talents and abilities. They benefit enormously from early intervention services, including physical, speech, and developmental therapies. Children with Down syndrome enjoy and benefit from social interactions with their typically developing peers.

The concept of the norm of reaction can be seen clearly in the outlook for children with Down syndrome. This condition, which occurs in about 1 of every 700 live births, is the most common chromosomal cause of mental retardation in the United States (Parker, Mai, Canfield et al., 2010). In the early part of the 20th century, children born with Down syndrome had a life expectancy of 9 years. Today, the average life expectancy of a person with Down syndrome is 50 and beyond (National Institutes of Health, 2014). Medical care, early and constant educational intervention, physical therapy, and a nurturing home environment have significant positive results for children with Down syndrome (Hazlett, Hammer, Hooper, & Kamphaus, 2011). Participation in a mainstreamed classroom environment has been shown to have significant benefits for these children's vocabulary, grammar, and certain memory skills. Under optimal conditions, individuals with Down syndrome are able to achieve a moderate degree of independence and to participate actively in the life of their schools, communities, and families. Although Down syndrome constrains the probable phenotype, there is a norm of reaction that results from a child's exposure to various degrees of environmental support (National Down Syndrome Society, 2013). Thus, the norm of reaction depends on the specific dynamic interaction of a given genotype in a particular environment.

FURTHER REFLECTION *What do you know about your genetic makeup? How would you find out more if you were interested?*

Based on your reading, how do you evaluate the contribution of genetics and environment to human behaviors? How do genetics and environment contribute to areas of human functioning such as intelligence, creativity, leadership, or sense of humor?

Normal Fetal Development

OBJECTIVE 3 Trace the process of prenatal development from fertilization through three trimesters of pregnancy, including an understanding of infertility, alternative means of reproduction, and related ethical considerations.

In the three trimesters of pregnancy, development unfolds from the cellular level of two merging gametes to the formation of complex physical, sensory, and neurological capacities.

Fertilization

One normal ejaculation contains several hundred million sperm. This large number is necessary to ensure **fertilization** because most sperm die on the way through the vagina and the uterus. Each microscopic sperm is composed of a pointed head and a tail. The head contains the genetic material necessary for reproduction. The tail moves like a whip as the sperm swims through the cervix and uterus and into the fallopian tubes. Swimming at the rate of 1 inch every 8 minutes, sperm may reach the egg in as little as 30 minutes, but the journey usually takes about 6 hours; sperm can stay alive in the uterus for up to 5 days.

In contrast to a man, who produces billions of sperm in a lifetime, a woman ordinarily releases just one ovum, or egg, each month, midway through the menstrual cycle. In a lifetime of approximately 40 fertile years, the average woman releases roughly 450 eggs. Each woman is born with her complete supply of eggs.

Like the sperm, the ovum is a single cell that contains genetic material. In comparison with body cells, the ovum is quite large

(0.12 millimeters), about the size of the period at the end of this sentence. When the ovum is mature, it is encased in a sac of fluid and floats to the surface of the ovary. The sac ruptures and releases the ovum into one of the two fallopian tubes. Millions of feathery, hair-like structures in the fallopian tube sweep around the ovum and gently move it toward the uterus.

Only one sperm can enter the egg. As the first sperm passes through the egg's cell membrane, a rapid change in the membrane's chemistry effectively locks out other sperm. If the ovum is not fertilized within the first 24 hours of its maturity, it begins to disintegrate and is shed along with the lining of the uterus in the next menstrual period.

Once inside the egg cell, the sperm loses its tail, and the head becomes a normal cell nucleus. The egg cell also goes through a final change in preparation for fertilization. The **gametes** (egg and sperm cells) contain 23 chromosomes, rather than the full set of 23 pairs. When the cell nuclei of the sperm and the ovum meet in the egg cytoplasm, their separate chromosomal material is integrated into a single set of 23 pairs of chromosomes. At this moment, all the information necessary to activate growth is contained in a single cell.

Paul Tople/Newscom/Tribune News Service/TWINSBURG/Ohio/USA

Identical twins have the same genotype; fraternal twins are no more alike genetically than other siblings. However, both kinds of twins share the same prenatal environment. These twins smile for a group photo at the 32nd annual Twins Days Festival in Twinsburg, Ohio.

Twins

The cell produced when the sperm has fertilized the egg is referred to as a **zygote**. The zygote travels down the fallopian tube and divides as it travels toward the uterus without growing larger. After about a week, this mass of cells implants in the uterus. Occasionally, this growing mass of cells divides in two and separates, forming two individuals with the same chromosomal composition. These individuals are referred to as **monozygotic** (MZ) twins, because they come from a single zygote. They are always of the same sex and are strikingly similar in physical appearance, a characteristic leading to the term **identical twins**.

Fraternal twins occur as a result of multiple ovulations in the same cycle. Each egg develops separately in the ovary, is shed and fertilized individually, and develops separately in the uterus. The result is **dizygotic** (DZ) twins—that is, two-egg twins. Actually, these twins are littermates and may be of different sexes. Genetically, they bear no more resemblance to one another than other children of the same parents. However, they share the same prenatal environment and a more common parenting environment than do most siblings who are born one or more years apart. This may account for the greater similarity in intelligence between DZ twins as compared to siblings shown in Figure 4.6. Approximately 34 in 1,000 live births are twins; 113.5 births in 100,000 are triplets or more. This rate for triplets is the lowest in 20 years. The ratio of multiple births is notably higher among mothers over age 30, possibly because older mothers are more likely to be using some type of fertility therapy (Hamilton et al., 2015).

Infertility and Alternative Means of Reproduction

Infertility, or the inability to conceive, can result from problems in the reproductive system of the man, the woman, or both. An estimated 12 percent of women in the United States between the ages of 15 and 44 face problems of infertility. The risk of infertility increases with age and is associated with exposure to toxins, including cigarette smoke, pesticides, chemical solvents, and fumes from anesthesia (NICHD, 2012a). Research on the emotional impact of infertility suggests that it is a major source of stress. The discovery of infertility may force a couple to reassess the meaning and purpose of their marriage. It may raise doubts in the couple about their self-worth; it often disrupts their satisfaction with their sexual relationship; and it often isolates them because of the difficulty of discussing this personal family problem with others (Haynes & Miller, 2003).

> I have been trying to conceive for 2 years. Each month, at ovulation, I am so sure this will be "the month." And then, like clockwork, my period comes and I spend at least a day feeling depressed. Sex has even become a chore for both me and my partner. This whole infertility roller coaster is definitely hurting our relationship and sex life. Well-meaning friends tell me it will happen when the time is right, but I don't know how to help our relationship in the meantime. (Peterson, 2001)

When couples perceive similar levels of distress about their infertility and are able to communicate with each other about it, they report higher levels of marital satisfaction (Peterson, Newton, & Rosen, 2003). However, it is not uncommon for husbands and wives to have different reactions to infertility and different levels of distress about it, which results in more strained marital relationships. The stressors associated with infertility may go on over a long period. Some couples undergo fertility treatments for years before conceiving or giving up on their hopes for a biologically related child. Over time, the impact of infertility can become increasingly stressful, leading to high levels of depression as various alternatives are tried and fail (Covington, 2015; M. P. McCarthy, 2008).

Although much of the literature focuses on the experiences of women, men have strong feelings of their own as the infertility persists (E. McCarthy, 2013). Edward describes one aspect of his distress, the lack of male friends or family with whom he can share his feelings.

> As infertility dragged on, my heart yearned to share my feelings with an understanding peer, another man who had either been where I was or one who was on the infertility roller coaster himself. I had experienced this type of mutual support during my training days as a chaplain, but now, I couldn't find the same type of safe haven to express my sense of utter loss, my anger, my grief, and my frustration that swirled around like a hurricane in my soul. In general, men experiencing grief have a lack of kinship with peers. (Dake, 2002, p. 49)

In addition to the emotional costs of treatment, there are substantial financial costs amounting to tens of thousands of dollars, most of which is not covered by insurance. Moreover, many procedures are unsuccessful. During 1 year of unprotected sexual relations, 90 percent of healthy couples achieve pregnancy. Data from 467 U.S. clinics reporting to the National Center for Chronic Disease Prevention and Health Promotion in 2013 provide a picture of the likelihood that a reproductive cycle using an **assisted reproductive technology** (ART) results in a live birth. The cycle begins with the fertilization of one or more ova using one of the techniques described in the **Applying Theory and Research to Life** box Reproductive Technologies. The 190,733 ART cycles performed at these reporting clinics resulted in 54,323 live births (deliveries of one or more living infants) and 67,996 infants. Over 1.5 percent of all infants born in the United States are now conceived using some form of ART (Centers for Disease Control and Prevention, 2015a). For more information about infertility and reproductive technologies, you may want to visit the website of the International Council on Infertility Information Dissemination at www.inciid.org.

On an encouraging note, longitudinal studies have compared children conceived through **artificial insemination**, **surrogacy**, and **in vitro fertilization** and those who are a product of natural conception. Results of these studies find that there are no differences in child adjustment in infancy, toddlerhood, or early school age among these groups (Golombok, Murray, Jadva, MacCallum, & Lycett, 2004; Golombok et al., 2011). Families with children conceived through alternative reproductive technologies have been compared with families with naturally conceived and adopted children. In general, parents of children conceived through both types of assisted reproduction showed more warmth and involvement with their children, higher levels of interaction, and lower levels of stress than the parents of children who were conceived naturally. Parents of adopted children typically scored in between the levels of the other two groups. In a comparison of parenting experiences for couples who conceived through a successful ART procedure and couples who conceived spontaneously, mothering experiences during the child's first year of life were more positive for the ART mothers. Difficulties with the birth, challenges associated with low-birth-weight babies, and difficulties soothing the babies were perceived as less stressful for the ART mothers than for mothers who conceived through spontaneous fertility (Repokari et al., 2006). In general, the research to date suggests a positive developmental trajectory for mother–infant relationships for infants conceived through in vitro fertilization.

Ethical Considerations of ART

ARTs have raised many legal and ethical questions.

1. One of these focuses on equitable access to these new technologies (Beckman & Harvey, 2005). A variety of social, medical, financial, and legal practices have resulted in limited access to ART for certain groups of marginalized women including unmarried women, women with alternative sexual orientations, poor women, and women whose ability to rear children is questioned, especially women with certain disabilities and older women (Brezina & Zhao, 2012; Kissel & Davey, 2012; Peterson, 2005). There is wide variability in funding for ART, including government and insurance sources, and insurers differ in the extent of coverage they will provide for these interventions.
2. As a result of fertility intervention, women in their 60s are having babies (*Sydney Morning Herald*, 2011). Ethical considerations have been raised about the use of medical technology to keep the birth window open at this advanced age. Concerns focus on the medical complications associated with pregnancy in older women and on whether older men and women can sustain effective parenting as their children move into adolescence while they enter later adulthood.
3. Another ethical concern involves attitudes about the acceptable use of reproductive technologies. For example, there is a debate about whether couples should be allowed to use reproductive technologies to select the sex of their child or to select for or against certain genetic conditions that are not life threatening such as deafness or Down syndrome (Hollingsworth, 2005; Johnston, 2005).
4. A fourth ethical concern involves the lack of information for consumers in order to make a reasoned decision about whether to elect to use reproductive technologies. Information about risks, costs, legal considerations,

APPLYING THEORY AND RESEARCH TO LIFE

Reproductive Technologies

Much of the data about reproductive technology focuses on strategies for artificially fertilizing ova and transferring them to the uterus for the prenatal period. Many websites are available for advice, exchange of information, and encouragement to individuals who are using or thinking about using these new technologies. The following sections describe reproductive technologies in use today.

Artificial Insemination

This is an old form of reproductive technology that is commonly used in animal husbandry and more recently has been applied to human fertilization. Sperm that have been donated and frozen are injected into a woman at the time of her ovulation. The most successful approach is to inject the sperm directly into the uterus (IUI, *intrauterine insemination*), thus bypassing the potentially destructive cervical environment.

Typically, the male partner is the source of the sperm; however, this is not necessary. Some sperm banks keep the donors' characteristics on file, which enables the woman to select the sperm of a donor whose features she desires in her offspring. Other banks blend sperm, so that the recipient cannot trace the donor's identity. In one recent case, a woman froze her husband's sperm and was able to conceive his child using artificial insemination after his death. Success rate: 5 percent to 30 percent per cycle using IUI (IVF-infertility.com, 2013).

Fertility Drugs

Ovulation induction is the artificial stimulation of the ovaries to produce eggs using **fertility drugs**. There is about a 90 percent chance that the ovaries can be made to work with the right drug(s) as long as the woman is not suffering ovarian failure (IVF-infertility.com, 2013). The administration of fertility drugs usually results in the release of multiple eggs at a cycle, increasing the chances that one egg will be fertilized. In about 20 percent of cases, multiple births result. Most other assisted reproductive technologies begin with this step (i.e., using some form of medication to stimulate the ovaries to produce eggs). If this is successful, decisions must be made about how many eggs to fertilize and how many embryos to transfer to the uterus. For male infertility, when the cause of the infertility is diagnosed as due to a specific infection, or chemical or hormonal imbalance, medical treatments can be successful (UCSF Medical Center, 2015).

In Vitro Fertilization (Fertilization in an Artificial Environment)

In vitro fertilization occurs when eggs are removed from the ovary and placed in a petri dish inside an incubator. A few drops of sperm are then added to the dish. If the eggs are fertilized and the cells begin to divide, they are returned to the woman's uterus or implanted in the uterus of another woman for subsequent development. Typically, two or three embryos are transferred at once in hopes that at least one will implant and mature. Success rates for this type of ART can vary depending on whether the eggs are donated or from a nondonor woman, the age of the woman who is donating the eggs, and whether the embryo is implanted immediately or after having been frozen. The overall success rate for live births resulting from ART cycles started in 2013 was 33 percent. This figure reflects only cycles intended to be used for immediate implantation, not cycles intended to be frozen and stored for later use (Centers for Disease Control and Prevention, 2015).

Intracytoplasmic Sperm Injection

A modification of in vitro fertilization is intracytoplasmic sperm injection, in which a sperm is injected directly into the egg. This procedure is used when there is a very low sperm count or nonmotile sperm. Embryos produced by in vitro fertilization can be frozen for future use if the initial pregnancy does not reach full term.

Gamete Intrafallopian Transfer (GIFT)

Gamete intrafallopian transfer (GIFT), involves using a fiber optic instrument called a laparoscope to guide the transfer of unfertilized eggs and sperm (gametes) into the woman's fallopian tubes through small incisions in her abdomen. Fertilization takes place as it normally would, within the woman's reproductive system. These eggs and sperm may come from the couple or from other donors. Thus, the fetus may be genetically related to the man or the woman in the couple or to neither.

In Vivo Fertilization (Fertilization in a Living Body)

In vivo fertilization (fertilization in a living body) is when partners involve another woman in the conception. The second woman, who has demonstrated her fertility, is artificially inseminated with the man's sperm. Once an embryo has formed, it is transferred to the first woman's uterus, which becomes the gestational environment. The child is therefore genetically related to the man, but not to the woman.

Surrogate Mother

There are two types of surrogacy, traditional and gestational. In the traditional surrogacy, sperm from an infertile woman's husband are injected into the surrogate mother during the time of her monthly ovulation. This is repeated each month until the surrogate becomes pregnant. The surrogate mother bears the child and returns it to the couple at birth. In gestational surrogacy, the couple produces the embryo through IVF and the resulting embryo is implanted in the surrogate. Surrogacy is an expensive and legally complicated procedure. Not all states allow surrogacy, and each state has its own regulations regarding its execution. Although the use of surrogacy appears to be increasing, there are no official statistical data available to the public about the number of births in the United States

(Continued on next page)

APPLYING THEORY AND RESEARCH TO LIFE (continued)

attributed to surrogacy. One report found that the number of births in the United States through gestational surrogacy increased from 738 in 2004 to 1,593 in 2011 (Cohen, 2013).

Critical Thinking Questions

1. Summarize the costs associated with these various ARTs. You will have to go to other sources beyond this book to find out about this.
2. Evaluate the risks associated with each method. Again, you will have to draw on additional resources and use your critical thinking skills to address this question.
3. Explain the different reasons that people may have for wanting to explore ARTs. What medical or personal circumstances might lead to an individual or a couple to choose one method over another?
4. Imagine that you are advising someone who is thinking about using ART. Describe the factors you would want the person to be aware of. What would you point out related to health risks, costs, and success rates?
5. Based on your reading and your experiences, hypothesize why someone might prefer to use one of these technologies instead of adopting a child.

and effectiveness is often not available or not accurate (Wingert, Harvey, Duncan, & Berry, 2005).

5. Questions are raised about the limits that should be placed on the production and use of embryos in vitro. Should scientists be permitted to produce embryos from frozen sperm and egg cells for purposes other than implantation? Thousands of frozen embryos are held in various medical and laboratory facilities in the United States. Research on embryos is important for further understanding of the expression of genetic diseases, for understanding the factors associated with miscarriages, and for improving reproductive technologies. Various countries as well as states within the United States differ in their laws governing the use, preservation, and ownership of embryos produced through ART. Ethical and legal questions are being raised about the rights of parents to determine the fate of these embryos, the embryos' rights to protection and inheritance, and the responsibility of institutes and laboratories to ensure the proper use of the embryos (Krones et al., 2006).
6. Issues regarding claims to parenthood are called into question. The husband of a woman who is planning to be artificially inseminated must consent to the procedure and agree to assume legal guardianship of the offspring. But are there parental rights associated with being sperm and egg donors? Surrogacy is a growing international practice that has complex ethical implications, including the legal, financial, and kinship aspects of giving birth to another couple's child.

Countries differ in the extent to which they have developed comprehensive guidelines and legislation to address these varied ethical considerations. The state of Victoria, Australia, was a leader in introducing comprehensive legislation to regulate the use of ART in 1988. Contemporary ART legislation in Victoria is guided by the following ethical principles:

> (1) the welfare and interests of persons born or to be born as a result of treatment procedures are paramount; (2) at no time should the use of treatment procedures be for the purpose of exploiting, in trade or otherwise (a) the reproductive capabilities of men or women, or (b) children born as a result of treatment procedures; (3) children born as a result of the use of donated gametes have a right to information about their genetic parents; (4) the health and wellbeing of persons undergoing treatment procedures must be protected at all times; and (5) persons seeking to undergo treatment procedures must not be discriminated against on the basis of their sexual orientation, marital status, race or religion. (Johnson, 2014)

Adoption

Adoption is an alternative to biological reproduction for those who want to be parents. In 2014, 107,918 children in foster care in the United States were waiting to be adopted. In that year, 50,644 or slightly less than 50 percent were adopted. For these children, the median length of time from the end of their parents' rights to the time they were adopted was 8.7 months (U.S. Department of Health and Human Services, 2015).

Adoption options include international adoption, adoption from a child in foster care, and adoption from a private agency. A national survey of parents of over 1.8 million adopted children conducted by the National Center for Family and Marriage Research found that across all three of these alternatives, the most common reasons parents gave for adopting a child were: (1) the desire to give a permanent family and home to a child in need; (2) a desire to expand their family; and (3) an inability to have a biologically related child (Ela, 2011).

Most agencies that provide adoption services suggest that couples who have undergone treatment for infertility need to cope with the grief and disappointment of unsuccessful outcomes before engaging in the adoption process. Once the alternative of adoption is being considered, new decisions must be faced including international versus domestic adoption, age of child, racial preferences, and adoption from a private service or a public agency. The adoption process typically includes a 3- to 6-month home study in which a social worker gathers information about the adoptive parents. This process allows the adoptive parents to consider the decision to adopt from many angles and also allows the agency to reach an informed assessment of whether the prospective parents will be able to provide a caring, supportive family for the adoptive child (Arcus & Chambers, 2008; Pertman, 2011).

FURTHER REFLECTION *Imagine that you were faced with the challenge of infertility. How might you cope? What alternatives would you be willing to consider: childlessness, adoption, fertility drugs, artificial reproductive technologies, surrogacy? How important is it to you to have a genetically related child?*

Development in the First Trimester

The period of pregnancy—typically 40 weeks after the last menstrual period, or 38 weeks from ovulation—is often conceptualized in three 3-month periods called **trimesters**. Perhaps because development is so rapid and dramatic during the first trimester, it is divided further into the **germinal period**, the **embroynic period**, and the **fetal period**. Each trimester brings changes in the status of the developing fetus and its supporting systems (Moore, Persaud, Torchia, 2015). These changes are summarized briefly in Table 4.2. The pregnant woman also experiences changes during the trimesters. In the first trimester, many women are not certain that they are pregnant. By the last trimester, though, the woman is usually certain, and so is everyone else! There are many apps available to follow the process of pregnancy and prenatal development. Four that are widely recommended are WebMdPregnancy, The pregnancy companion, The Ovia, and I am totally pregnant. These apps help women and their partners understand the biological changes associated with pregnancy, likely physical symptoms, images and characteristics of the developing fetus, questions to ask one's physician, suggestions for maintaining good health and fitness during pregnancy, and access to additional resources.

The Germinal Period

After fertilization, the egg begins to divide. At this time, the cell material is referred to as a zygote until implantation. The first series of cell divisions does not increase the mass of the cells, nor do the cells take on specialized functions; rather, the cell material is redistributed among several parts. These are the cells referred to earlier in the chapter as *stem cells*. When implantation is successful, by the 6th day after fertilization, the egg makes contact with the lining of the uterus and begins to attach itself there. At this point, the cells are referred to as an **embryo**. Sometimes, the egg does not reach the uterus but attaches itself to the fallopian tube or even to some area of the intestine. This can be a life-threatening condition. The embryo may grow in these locations until the organ ruptures.

The Embryonic Period

The 3 weeks following implantation are devoted primarily to elaboration of the supportive elements that will house the embryo. An **amniotic sac** surrounds the embryo and fills with a clear, watery fluid. This fluid acts as a cushion that buffers the embryo and permits it to move about and change position. Once the embryo is firmly implanted in the uterus, special cells in the placenta produce a hormone that maintains the uterine lining. This hormone is excreted through the kidneys, so a urine sample can be evaluated to determine its presence. Home pregnancy tests are based on the detection of this hormone in a small drop of urine and are accurate 1 or 2 days after implantation. A large number of pregnancies are spontaneously aborted in these early weeks, usually as a result of some major abnormalities of the embryo.

The **placenta** is an organ that is newly formed with each pregnancy and is expelled at birth. Nutrients necessary for the embryo's growth pass through the placenta, as does the embryo's waste, which then passes into the mother's blood. Thus, the placenta is an exchange station at which adult material is synthesized for the embryo's use and foreign materials harmful to the embryo's development can be screened out. However, this screening is imperfect. Even though the mother's blood and the embryo's blood are separated by independent systems, the placenta permits the two systems to come close enough that oxygen and nutrients from the mother's blood can enter the fetal system and waste products from the fetal system can be removed. In the process, certain substances in the mother's system may affect the fetal system.

Agents that can produce malformations in the fetus while the tissues and organs are forming are referred to as **teratogens**. Teratogens have a wide variety of forms, such as viruses; medicines, alcohol, and other drugs that a pregnant woman takes; and **environmental toxins**. During the first trimester—especially weeks 3 through 9—the embryo is particularly sensitive to the disruptive influences of teratogens (see FIGURE 4.8 ▶).

Table 4.2 **Major Developments in Fetal Growth During the Three Trimesters**

First Trimester	Second Trimester	Third Trimester
Fertilization	Sucking and swallowing	Nervous system matures
Growth of the amniotic sac	Preference for sweet taste	Coordination of sucking and swallowing
Growth of the placenta	Skin ridges on fingers and toes	Mechanisms for regulating body temperature
Emergence of body parts	Hair on scalp, eyebrows, back, arms, legs	More efficient digestion and excretion
Differentiation of sex organs	Sensitivity to touch, taste, light	Degeneration of the placenta toward the end of the ninth month
Initial formation of central nervous system	Sucks thumb	9-month average size: 20 inches, 7 to 7½ pounds
Movement	6-month average size: 10 inches, 2 pounds	
Grasp reflex		
Babinski reflex		
Heartbeat		
3-month average size: 3 inches, about 2/5 ounce

FIGURE 4.8▶ CRITICAL PERIODS IN PRENATAL DEVELOPMENT During the first 2 weeks of development, the embryo is usually not susceptible to teratogens. During these predifferentiation stages, a substance either damages all or most of the cells of the embryo, resulting in its death, or damages only a few cells, allowing the embryo to recover without developing defects. Dark bars denote highly sensitive periods for particular organs or organ systems; light bars indicate stages that are less sensitive to teratogens. Severe mental retardation may result from the exposure of the embryo or fetus to teratogenic agents, such as high levels of radiation, from the 8th to the 16th week.

Source: Rathus, Childhood and Adolescence, 6e, 9781305504592, page 96 figure 3.05

In the third and fourth weeks, the embryo's cells differentiate rapidly, taking on the specialized structures that will permit them to carry out their unique functions in the body. Similar cells are grouped into tissues that gradually emerge as body organs. The first essential changes include the establishment of the body form as an elongated cylinder and the formation of structures that will eventually become the brain and the heart. The neural tube, which is the structural basis of the central nervous system (CNS), begins to take shape at the end of the third week after conception. Cells in the neural tube are produced at the miraculous rate of 250,000 a minute over the first 5 weeks, as the tube is differentiated into five bulges that are the forerunners of the major subdivisions of the brain.

The central nervous system begins to develop early in the prenatal period and continues to develop throughout childhood and adolescence. Most of the neurons that will make up the cerebral cortex are produced by the end of the second trimester. By birth, the infant's brain contains roughly 100 billion neurons, ready to be linked and organized into networks as the infant responds to environmental stimulation and patterned experience (Aoki & Siekevitz, 1988; Lagercrantz, Hanson, Ment, & Peebles, 2010).

By the end of the fourth week, the head, the upper trunk, and the lower trunk are visible, as are the limb buds and the forerunners of the forebrain, midbrain, hindbrain, eyes, and ears. The embryo has increased 50 times in length and 40,000 times in weight since the moment of fertilization.

By the end of the second month, the embryo looks quite human. It weighs about 2.25 grams and is about 28 millimeters (1 inch) long. Almost all the internal organs are formed, as are the external features of the face, limbs, fingers, and toes. At 8 weeks, the embryo will respond to mild stimulation. The embryonic period ends about 10 weeks after the last menstrual period—most of the essential structures are formed by this time. The term **fetus** is used from this point until birth.

The Fetal Period

In the third month, the fetus grows to 3 inches, and its weight increases to 14 grams. The head is about one third of the total body length. During this month, the fetus assumes the *fetal position*, arms curled up toward the face and knees bent in to the stomach. The eyelids are fused.

A dramatic change takes place in the sex organs during this period. All embryos go through a bisexual stage, during which no sex-linked characteristics can be discerned. Both female and male embryos have a surface mass that becomes the testes in male fetuses and eventually deteriorates in female fetuses, when new sex cells grow to form the ovaries. Both male and female embryos have two sets of sex ducts. In male fetuses, the sperm ducts develop and the female ducts dissolve. In female fetuses, the fallopian tubes, the uterus, and the vagina develop, and the other ducts degenerate. Finally, both male and female embryos have a conical area that is the outlet for the bladder duct. In males this area forms into the penis and scrotum. In females, it remains to form the clitoris, which is surrounded by the genital swellings of the labia majora.

Differentiation of the male and female genitalia is guided by genetic information. In the presence of the maleness gene, SRY, the undifferentiated embryonic tissue is transformed into the testes. The testes then produce gonadal steroid hormones that facilitate the further elaboration of male genitalia and internal reproductive structures. Genes carried on the X chromosome are thought to guide the formation of the ovaries (Crooks & Baur, 2016).

The genetic factors that produce the differentiation of the fetus as male or female appear to influence more than the formation of the reproductive organs and the production of hormones. Research on the organization and structure of the brain suggests that during fetal and early postnatal development, sex hormones direct male and female brains along slightly different paths.

> The brain is in reality not a unitary organ like the liver or the kidney. It is a compilation of multiple independent yet interacting groups of cells that are subject to both external and internal factors. …. As a result, it is quite literally impossible for the brain to take on a uniform "maleness" or "femaleness." Instead, the brain is a mix of relative degrees of masculinization in some areas and feminization in others. On average, there are likely to be some areas that are more strongly feminized in a female and others that are more strongly masculinized in a male, but averages are never predictive of an individual's profile. Moreover, a mosaic is not a blend—there is not a continuum of maleness to femaleness—and there are many parameters that are neutral in regard to sex, with no consistent differences between males and females.
>
> Evolutionarily, the creation of a **maleness–femaleness** mosaic within one brain makes sense, providing organisms with greater variability and therefore adaptability to changing environments. (McCarthy, 2015)

Although males and females are very similar in most psychological variables, and in particular have similar distributions in measured intelligence, studies by numerous researchers have shown that sex differences in hormonal levels influence differences in specific problem-solving areas and intellectual strengths. Some of the areas in which males and females have been shown to differ include verbal ability, visual-spatial ability, and mathematical ability. We are still not sure what the route is from the developing fetal brain structure to cognitive functioning in childhood and beyond, but it is increasingly clear that anatomical variations in regions of the brain and their interconnections are tied to sex-linked variations in certain specialized problem-solving capacities (Kimura, 2002, 2004).

The 3-month-old fetus moves spontaneously and has both a grasp reflex and a Babinski reflex, in which the toes extend and fan out in response to a mild stroke on the sole of the foot. When an amplified stethoscope, called a Doppler, is placed on the mother's abdomen, the fetal heartbeat can be heard through the uterine wall by the expectant parents as well as the physician and nurse. For expectant parents, listening to the fetal heartbeat is one of the first experiences that transforms the fetus from something abstract and remote to a concrete, vital reality.

Guigoz/Petit Format/Science Source

At 16 weeks, the fetus is about 6.4 inches (16 cm) long and is clearly recognizable as a human child. The fetus has assumed what is known as the "fetal position"—arms curled up near the head and legs bent in toward the stomach—a position that remains part of the human behavioral repertoire throughout life.

fills with amniotic fluid; thus, the sense of smell is probably not functional until birth.

The external ear canal is filled with fluid. The fetus does not respond to sound until the third trimester; however, the semicircular canals of the inner ear are sensitive to stimulation. The nerve fibers that connect the retina to the brain are developed by 6 months, and infants born prematurely at this time respond to light.

At 25 weeks, the fetus functions well within its uterine environment. It swallows, digests, excretes, moves about, sucks its thumb, rests, and grows. However, the nervous system, which begins to develop at 3 weeks, is still not mature enough to coordinate the many systems that must function simultaneously to ensure survival. The outlook for survival of the 22- to 24-week-old fetus is improving, especially if the infant is treated in a special care center

Development in the Second Trimester

During the second trimester, the average fetus grows to 10 inches and increases in weight to almost 2 pounds. The fetus continues to grow at the rate of about an inch every 10 days from the fifth month until the end of the pregnancy. During this trimester, the uterus itself begins to stretch and grow. It rises into the mother's abdominal cavity and expands until, by the end of the ninth month, it is pushing against the ribs and diaphragm. The reality of a growing life becomes more evident to the pregnant woman during this trimester as she observes the changes in her body and experiences the early fetal movements, called **quickening**. These movements first feel like light bubbles or twitches; later, they can be identified as the foot, elbow, or fist of the restless resident.

During the fourth month, the fetus begins to suck and swallow. Whenever the fetus opens its mouth, amniotic fluid enters and cycles through the system. This fluid provides some nutrients in addition to those absorbed through the placenta. The 4-month-old fetus shows some preference for a sweet taste: If sugar is introduced into the amniotic fluid, it will swallow the fluid at a faster rate.

In the fifth month, the skin begins to thicken, and a cheesy coating of dead cells and oil, the *vernix caseosa*, covers the skin. The individuality of the fetus is marked by the pattern of skin ridges on the fingers and toes. Hair covers the scalp, eyebrows, back, arms, and legs.

The sensory receptors of the fetus are well established by the end of the sixth month. The fetus is sensitive to touch and may react to it with a muscle movement. It will also stick out its tongue in response to a bitter taste. Throughout the sixth month, the nostrils are plugged by skin cells. When these cells dissolve, the nose

James Stevenson/Science Source

At 23 weeks, the fetus is about 12 inches (30 cm) long, still small enough to have room to swim about in the expanding uterus. As any pregnant woman will tell you, the fetus is active at this stage, kicking, grasping, waving its arms, and turning over.

where more aggressive interventions are applied. In one study, 39 percent of infants born at 22 to 24 weeks of gestational age survived, with survival rates varying notably depending on the kind of center where the infants were treated. For infants born at 25 to 27 weeks, the survival rate was 81 percent (Smith et al., 2012). Researchers in the United Kingdom have found that the 22- to 24-week-old babies who are born at medical centers that specialize in the care of very small babies have a better chance of survival than those who are transferred from smaller hospitals to these centers after birth (Salter, 2014). These advances in the treatment of extremely pre-term infants are raising new questions about policies related to fetal viability and its relationship to abortion practices.

Development in the Third Trimester

In the last trimester, the average fetus grows from 10 to 20 inches and increases in weight from 2 to 7 or 7½ pounds. These increases in body size and weight are paralleled by a maturation of the central nervous system. From 20 to 28 weeks of gestational age, fetal heart rate declines and variability and accelerations in heart rate increase. In the third trimester, there are longer periods of quiet between fetal movements. By combining recordings from ultrasound and monitoring of fetal heart rate, patterns of fetal behavioral states have been documented. They include periods of quiet, similar to non-REM sleep in newborns; periods of frequent movement with sleep-like heartbeat, similar to REM sleep; periods of quiet wakefulness; and periods of active wakefulness (Nijhuis, 2003). Moreover, fetal heart rate and fetal movement become increasingly coordinated. These patterns suggest a critical integration of the somatic and cardiac processes within the central nervous system. At some point between 28 and 32 weeks, these patterns of increase stop and are replaced by a leveling off or slight decrease. This pattern is interpreted to mean that a certain critical level of neurological maturation is in place by 32 weeks. Evidence to support this idea is found in the cognitive competence of preterm infants who are born at about 32 weeks (DiPietro et al., 2004; DiPietro et al., 2010).

Additional evidence of cognitive maturation is provided by studies of fetal memory. By the age of 30 weeks gestational age, the fetus appears to recognize and remember the sensation of a vibroacoustic stimulus that is applied to the mother's abdomen. Fetal movement in the second following the stimulus is taken as evidence of a response. The absence of fetal movement on four trials following several consecutive positive responses is taken as evidence of habituation or familiarity with the stimulus. By 38 weeks of gestational age, the fetus recognizes these vibroacoustic stimuli even 4 weeks after the last testing session (Dirix, Nijhuis, Jongsma, & Hornstra, 2009).

Research on fetal sensitivity to sound has a long history. A number of studies have demonstrated that the fetus is sensitive to auditory stimulation in the form of music as well as speech. A fetus experiences its mother's speech sounds during the third trimester, becoming familiar with the sound of her voice and the features of her spoken language (DeCasper et al., 1994). Neural networks sensitive to properties of the mother's voice and native-language speech are being formed during the prenatal period (Kisilevsky et al., 2009).

In one study, pregnant women played a recording of *Twinkle Twinkle Little Star* five times a week at loud volume beginning in the eighth month of gestational age. At birth, and again at 4 months after birth, evidence from EEG recordings demonstrated that the babies recognized the melody, and reacted differently when notes were identical or changed from the tune they heard prenatally (Partanen, Kujala, Tervaniemi, & Huotilainen, 2013). Studies of 36- to 39-week-old fetuses have found that they are sensitive to changes in low-pitched musical notes, to pulsing as compared to continuous sounds, and to changes in speech sounds (Byers-Heinlein, Burns, & Werker, 2010: Groome et al., 2000; Lecanuet, Graniere- Deferre, Jacquet, & DeCasper, 2000).

Advantages of a Full-Term Fetus

The advantages that a full-term fetus has over a premature, 28-week-old fetus include (1) the ability to begin and maintain regular breathing; (2) a stronger sucking response; (3) well-coordinated swallowing movements; (4) stronger peristalsis and, therefore, more efficient digestion and waste excretion; and (5) a more fully balanced control of body temperature.

The full-term fetus has been able to take advantage of minerals in the mother's diet for the formation of tooth enamel. As the placenta begins to degenerate in the last month of pregnancy, antibodies against various diseases that have been formed in the mother's blood pass into the fetal bloodstream. They provide the fetus with immunity to many diseases during the first few months of life.

The uterus cannot serve indefinitely as the home of the fetus. Several factors lead to the eventual termination of the fetal-uterine relationship. First, as the placenta degenerates, antibodies that form in both the mother's and the fetus's blood would destroy the blood of the other. Second, because the placenta does not grow much larger than 2 pounds, the fetus, as it reaches its maximum size, cannot obtain enough nutrients to sustain life. Third, the fetal head cannot grow much larger than the pelvic opening without endangering the brain in the birth process. Even though soft connecting membranes permit the skull plates to overlap, head size is a factor that limits fetal growth. The photo in this section shows the footprints of an infant born prematurely and an infant who has reached full gestational age.

Late in pregnancy, the fetal brain begins to produce hormones that increase the production of estrogen in the placenta. This, in turn, leads to a shift from mild to strong uterine contractions, which result in dilation of the cervix, rupture of the amniotic sac, and delivery (Cunningham et al., 2014; Nathanielsz, 1996). The approximate time from conception to birth is 38 weeks. However, there is variability in the duration of pregnancies and in the size of full-term infants, even infants born to the same mother.

FURTHER REFLECTION *Suppose your work exposed you to environmental toxins that might have a negative impact on your unborn child. What would you do?*

These are the birth footprints of a baby born prematurely at 23 weeks, and one born at a full 40-week gestational age.

The Birth Process

OBJECTIVE 4 Describe the birth process and analyze factors that contribute to infant mortality.

Birth is initiated by involuntary contractions of the uterine muscles, commonly referred to as **labor**. The length of time from the beginning of labor to the birth of the infant is highly variable. The average time is 14 hours for women undergoing their first labor and 8 hours for women undergoing later labors.

The uterine contractions serve two central functions: *effacement* and *dilation*. **Effacement**, or thinning, is the shortening of the cervical canal. **Dilation** is the gradual enlargement of the cervix from an opening only millimeters wide to one of about 10 centimeters—large enough for the baby to pass through. Effacement and dilation occur without deliberate effort by the mother. Once the cervix is fully enlarged, the mother can assist in the birth by exerting pressure on the abdominal walls of the uterus. The baby, too, helps in the birth process by squirming, turning its head, and pushing against the birth canal.

Stages of Labor

The medical profession describes three stages of labor. The first stage begins with the onset of uterine contractions and ends with the full dilation of the cervix; this is the longest stage. The second stage involves the expulsion of the fetus. It begins at full dilation and ends with the delivery of the baby. The third stage begins with delivery and ends with the expulsion of the placenta. This stage usually lasts 5 to 10 minutes.

These three stages of labor do not precisely parallel the personal experience of childbirth. For example, although the expulsion of the placenta is considered a unique stage of labor in the medical model, it is rarely mentioned in women's accounts of their birth experiences. On the other hand, many of the signs of impending labor that occur in the last weeks of pregnancy are often included in women's accounts of labor.

In terms of the psychological adaptation to the birth process, labor can be viewed as having five phases: (1) early signs that labor is approaching; (2) strong, regular uterine contractions, signaling that labor has begun and generally accompanied by a move from the home to the hospital or birthing center; (3) the transition phase, during which contractions are strong, rest times between contractions are short, and women experience the greatest difficulty or discomfort; (4) the birth process, which allows the mother's active participation in the delivery and is generally accompanied by a move from the labor area to the more sterile delivery room; and (5) the postpartum period, which involves the initial interactions with the newborn, physiological changes that mark a return to the prepregnant state, and the return home.

Cesarean Delivery

Sometimes a normal, spontaneous vaginal delivery would be dangerous to the mother or the newborn (Cunningham et al., 2014). One alternative is to remove the baby surgically through an incision in the uterine wall, a procedure called **cesarean section**. The incidence of cesarean deliveries in the United States increased from 5.5 percent of births in 1970 to 33 percent in 2013 (Martin et al., 2015). Cesarean deliveries may be planned or unplanned. The procedure may be used if labor is severely prolonged and the fetus appears to be at risk due to lack of oxygen. It may also be used when the infant is in the breech position (feet or buttocks first rather than head first) or if the mother's pelvis is too small for the infant's head to pass through. Physicians often recommend a repeat cesarean if the woman has delivered by cesarean section before. The rate of cesarean deliveries is higher for mothers age 30 and older than for younger mothers.

The cesarean delivery makes childbirth a surgical procedure, requiring anesthetics, intravenous feeding of the mother, and a prolonged recovery period. Although the procedure undoubtedly saves many infants and mothers who would not survive vaginal childbirth, there is some concern that it is being misused for the convenience of health professionals or busy mothers who want to be able to schedule deliveries and thus avoid waiting for the unpredictable onset of labor. In a national goal statement, *Healthy People 2020*, the U.S. Public Health Service called for a reduction of the national cesarean rate for both first-time deliveries and for births following a cesarean to an overall rate of 15 percent (U.S. Department of Health and Human Services, 2010)—a goal implying that a substantial number of the current cesarean procedures are not necessary.

Infant Mortality

The **infant mortality rate** is the number of infants who die during the first year of life per 1,000 live births during that year. In 2013, the U.S. rate was estimated at 5.96 deaths per 1,000 live births (Mathews, MacDorman, & Thoma, 2015). The rate for non-Hispanic Black babies in the United States in 2013—11.11 deaths per 1,000 live births—was higher than the infant mortality rates in countries such as Chile, Botswana, Cuba, Serbia, and Poland that are considered economically emergent nations (Central Intelligence Agency, 2015).

Roughly two thirds of infant deaths occur during the first month after birth. Most of these deaths result from severe birth defects, premature birth, or **sudden infant death syndrome** (SIDS), in which apparently healthy babies are put to bed and are later found dead with no clear explanation, even after autopsy.

Infant mortality rates are influenced by many factors, including the (1) frequency of birth complications; (2) robustness of the infants who are being born, which is influenced by their prenatal nutrition and degree of exposure to viruses or bacteria, damaging X rays, drugs, and other teratogens; (3) mother's age; and (4) facilities that are available for prenatal and newborn care. Infant mortality rates are 25 times higher for infants born at birth weights below 2500 grams than for infants born at 2500 grams or more. If the conditions leading to prematurity and associated low birth weight could be altered, the U.S. infant mortality rate would be significantly improved (Mathews, MacDorman, & Thoma, 2015).

Infant mortality rates vary from one country and region of the world to another. In 2015, the infant mortality rate in Japan was 2.08, but in that same year, the infant mortality rate in 13 other countries of the world was more than 70 (The Central Intelligence Agency, 2015). The United States, with all its resources and advanced technology, ranks behind other industrialized countries, including Australia, Canada, France, Germany, Israel, Italy, Japan, the Netherlands, South Korea, Spain, Switzerland, and the United Kingdom. Within the United States, regional infant mortality rates range from a low of 4.18 per 1,000 in the state of Massachusetts, to a high of 9.60 in Mississippi (Mathews, MacDorman, & Thoma, 2015).

The density of low-income populations, availability of educational materials on the impact of diet and drugs on the developing fetus, and adequacy of medical facilities for high-risk newborns all contribute to the regional variations in infant death rates among populations of different incomes. Children conceived in poverty are at the greatest risk of infant mortality. Their mothers receive poorer quality prenatal care and are exposed to more dangerous environmental and health factors during the prenatal period than are mothers of children conceived in more advantaged families. The chances that any one infant will survive the stresses of birth depend on the convergence of biological, environmental, cultural, and economic influences on the child's intrauterine growth, delivery, and postnatal care.

FURTHER REFLECTION *How do you account for the fact that the United States is behind so many other industrialized countries in the rate of infant mortality? Design an intervention that would contribute to lowering infant mortality rates in the United States.*

The Mother, the Fetus, and the Psychosocial Environment

OBJECTIVE 5 Analyze ways that the pregnant woman and the developing fetus influence each other, focusing on how pregnancy affects a childbearing woman and expectant father, and the impact of environmental influences on fetal growth, such as a woman's age, drug use, nutrition, environmental toxins, and stress.

The course of prenatal development is guided by genetic information that unfolds in the context of the pregnant woman's biopsychosocial environment. A woman's health, her attitudes toward pregnancy and childbirth, her lifestyle, the resources available to her during her pregnancy, and the behavior demanded of her by her culture all influence her sense of well-being. Many of these same factors may directly affect the health and growth of the fetus. In the next section, we discuss the impact of the fetus on the pregnant woman, including how the pregnancy might affect the infant's father and his relationship to the mother. The subsequent section focuses on the impact of the pregnant woman on the fetus and the many factors that contribute to the quality of the intrauterine environment.

The Impact of the Fetus on the Pregnant Woman

Consider some of the ways in which a fetus influences a pregnant woman. In the following sections we consider physical changes, changes in roles and status, and changes in the woman's emotional state. Pregnancy initiates sweeping hormonal changes that prepare the uterus to host the developing fetus. Over the months of pregnancy, the uterus changes in size and shape, altering the woman's physical appearance and placing new pressures on internal organs. Beginning in the second trimester, women experience fetal movement. Research that focused on the synchrony between fetal movement and maternal heart rate showed that after about 20 weeks **gestational age** (the age of the fetus from the time of conception until birth), a regular pattern could be observed in which fetal movement is followed after 2 or 3 seconds by an increase in maternal heart rate. Fetal movement occurs about once every minute. Even when the pregnant woman is not aware of the movement, changes in heart rate following movement were observed. One can think of the fetus as making repeated and continuous signals that engage the mother's autonomic nervous system and thereby begin a process through which the mother's level of arousal is linked to the infant's state (DiPietro et al., 2006).

Pregnancy alters a woman's body image and her sense of well-being. Some women feel especially vigorous and energetic during much of their pregnancy; others experience distressing symptoms such as nausea, backache, swelling, headache, and irritability. Some women say they have difficulty remembering things during their last trimester. In some cases, pregnancy is accompanied by serious illnesses that threaten the mother's health. To learn more about physical changes that accompany pregnancy and recommendations for maintaining one's health during pregnancy, you may want to visit the website on pregnancy from Medline Plus, the resource of the U.S. National Library of Medicine, https://www.nlm.nih.gov/medlineplus/pregnancy.html.

Changes in Roles and Social Status

Women who become pregnant may be treated in new ways by people close to them and by their broader communities. Usually, fathers become more concerned for and supportive of their pregnant partners, and pregnant women may also be viewed in a new light by their peers. In some communities, adolescent girls who become pregnant feel ashamed or guilty and may be scorned. In others, becoming pregnant during adolescence is

Laurie's experience of pregnancy is closely tied to the reactions of her loving partner and the enthusiastic curiosity of her daughter, who will soon become an older sib.

viewed by the peer group as an accomplishment, a sign of maturity. Work settings differ in the ways they respond to the needs of pregnant women. Some settings may accommodate pregnant women by giving them lighter duties or fewer responsibilities. In other settings, pregnant women may be forced to take unpaid leave if they cannot perform physical tasks or to avoid exposure to harmful chemicals. Pregnancy may be viewed as an annoyance, something that is likely to interfere with productivity, or it may be viewed as one of many physical conditions that must be accommodated.

Within her family, a pregnant woman is likely to be treated with new levels of concern and care. By giving birth to a first child, a woman transforms her mother and father into grandparents and her brothers and sisters into uncles and aunts. Moreover, pregnancy may strengthen the gender identity of the baby's mother or father. Just as infertility threatens one's gender identity, becoming pregnant may be viewed as confirmation of a woman's femininity and a man's virility in impregnating her.

In some societies, pregnancy and childbirth confer special status on a woman. In Japan, for example, traditional values place motherhood above all other women's roles. When they become mothers, Japanese women begin to have an impact on government, community, and public life as the people who are especially responsible for molding and shaping the next generation. For Mexican American women, childbearing is likely to be viewed within a broad religious context. Despite their difficult economic and social conditions, women who are Mexican immigrants in the United States have relatively fewer low-birth-weight babies than mothers from other low-income groups. One explanation is that the strong value for *familialism* in Latino/a families brings forth substantial family support that buffers the pregnant woman from the adverse effects of poverty (Campos, et al., 2008; Sagrestano et al., 1999; Sherraden & Barrera, 1996). See the **Applying Theory and Research to Life** box that discusses the positive effects for the mother of having a doula or supportive companion during the labor and delivery.

Being Pregnant Changes a Woman's Emotional State

For most people, being pregnant is a very powerful experience. Thus it is no surprise that mothers and fathers have strong emotional reactions to pregnancy. A woman's attitude toward her unborn child may be pride, excitement, acceptance, or rejection. In most normal pregnancies, women may experience negative feelings such as anxiety and depression as well as positive feelings such as excitement and hopefulness. The normal physical changes of pregnancy may become a source of stress for a pregnant woman. These changes include feelings of nausea, being tired, having indigestion, or backaches. Changing hormone levels may result in sleeplessness, mood swings, and irritability.

In addition to these troubling physical symptoms, the expectant woman has recurring worries and fears about the childbirth experience, whether the baby will be healthy, and her own well-being. These fears may be accentuated if the woman has heard about problems with childbirth from friends, relatives, or health care professionals (March of Dimes, 2013). In one study, women who had attended childbirth classes were interviewed 4 weeks after they gave birth. Thirty-four percent of the women reported that their childbirth experience was traumatic, including many who had symptoms of post-traumatic stress disorder (Soet, Brack, & Dilorio, 2003). Among women who have had previous pregnancies, worries may focus on recollections about the difficulties of delivery and the health and care of the new baby (Melender, 2002). Some women receive troubling information during an ultrasound screening about possible fetal abnormalities. This information adds to anxiety during pregnancy (Brisch et al., 2003).

Certain psychosocial factors are associated with increased anxiety and depression during pregnancy, including exposure to stressors, lack of resources, the absence of a supportive partner, and experiencing an unwanted pregnancy. It is not uncommon for depression to be higher in the early months of pregnancy and then to decline in the months after the baby is born. Women who show the greatest drop in depression over the pregnancy have relatively more financial resources, more social support, and fewer other life stressors (Ritter, Hobfoll, Lavin, Cameron, & Hulsizer, 2000).

APPLYING THEORY AND RESEARCH TO LIFE

The Doula or Birth Companion

The idea of having a supportive companion available to women during childbirth has been formalized in the role of **doula**. The term *doula* comes from a Greek word for handmaiden, referring to the primary servant for the woman of the household. Before the introduction of hospital deliveries, most cultures had a role for a close female companion who accompanied a woman during childbirth. The contemporary doula is trained to offer information as well as physical and emotional support during labor, delivery, and the early weeks following childbirth. Her role is to remain at the side of the laboring mother to help her have a safe, reassuring childbirth experience. She does not take the place of the midwife, obstetrician, nurses, or the mother's partner (Doulas of North America, 2013). According to the Doula of North America website, when a doula is present during and after childbirth, "women report greater satisfaction with their birth experience, make more positive assessments of their babies, have fewer caesareans and requests fewer medical interventions, and (experience) less postpartum depression."

A review of 15 studies involving more than 12,000 women examined additional empirical support for the contribution of the doula in childbirth (Hodnett, 2003). The studies were conducted in Australia, Belgium, Botswana, Canada, Finland, France, Greece, Guatemala, Mexico, South Africa, and the United States, under very different hospital conditions. All of the studies contrasted the childbirth experiences of women who did and did not have a supportive companion available during labor and delivery. Mothers who were accompanied by a supportive companion had shorter labors and fewer obstetrical difficulties. The presence of the doula has been shown to reduce the incidence of low-birth weight infants. The presumption is that a woman who is attended by a doula has lower levels of anxiety, thus reducing the release of hormones that might contribute to obstetrical difficulties and neonatal distress (Corter & Fleming, 2002; Kozhimannil, Almanza, Vogelsang, & Hardeman, 2015).

The presence of a doula is especially valuable in cases where women would ordinarily labor alone with just the presence of the medical staff. In a study of low-income women who were at risk for adverse birth outcomes, one group that received support from a doula was compared to a group that chose not to receive this support. All the mothers had been enrolled in a *Healthy Moms, Healthy Babies* childbirth class for at least three sessions. Doula-assisted mothers were four times less likely to have a low birth weight (LBW) baby, two times less likely to experience a birth complication involving themselves or their baby, and significantly more likely to initiate breastfeeding (Gruber, Cupito, & Dobson, 2013). The benefit of the doula appears to endure beyond childbirth, contributing to increased maternal responsiveness and competence in the months following the birth ((McComish & Visger, 2009, Nommsen-Rivers, Mastergeorge, Hansen, Cullum, & Dewey, 2009). To find out more about doulas and their role as birth companions, visit DONA International at www.DONA.org.

Critical Thinking Questions

1. Explain why and how the presence of a supportive companion might shorten labor and ease delivery.
2. List some characteristics that would make a person an effective doula.
3. Design a study to evaluate the benefits of a doula in childbirth.
4. Analyze the characteristics of the U.S. birth culture that might prevent or support the inclusion of a doula as a component of prenatal care and childbirth.

Fathers' Involvement During Pregnancy

Just like women, men have diverse reactions to the idea of having children. Their reproductive behaviors reflect their own psychosocial maturity, their perceptions about the quality and stability of the relationships they are in, the stability of their employment, and their readiness to embrace the responsibilities of fatherhood. Some men worry about the economic ramifications of the impending birth. If they are unemployed or underemployed, they may worry about money, have low confidence, feel they are not worth much, or be fearful that the mother's income will decrease. And some men do not seem to take any responsibility for the pregnancy they are responsible for. In a study of an ethnically diverse sample of low-income men, 171 were aware of their responsibility for 424 pregnancies (Augustine, Nelson, & Edin, 2009). Among this sample, 47 percent described the pregnancies a result of "just not thinking." These men did not have a plan to have a child and did nothing to prevent it. In contrast, some men reported that having a child brought them a new level of self-respect. Dante, a 38-year-old African American father who had been living a high-risk lifestyle before the birth of his child, told researchers, "I know for a fact that if it wasn't for my son and I was just a single guy [without kids] my life would be chaos!" (Augustine et al., 2009, p. 109).

The many different types of relationships that are possible between a woman and her partner have implications for both the emotional state of the mother during pregnancy and the psychosocial development of the child. Research supports the idea of continuity between the quality of the relationship between the partners during the prenatal period and the quality of their parenting in the early years of childhood. This continuity in turn has implications for the child's growth and development. Partners who show high levels of negative interaction or detachment during the prenatal period have trouble providing an emotionally secure environment for their newborn child. Anger, mistrust, or avoidance between partners are all likely to be a source of stress for a pregnant woman.

In contrast, couples characterized by positive mutuality, partner autonomy, and the ability to confront problems and regulate negative affect create a positive emotional climate for the pregnancy. Feelings of safety, security, and being loved and valued within a relationship can contribute to a woman's ability to manage the other worries that are associated with her pregnancy and delivery.

In the first trimester, involved fathers are able to hear the fetal heartbeat amplified through the Doppler. Through the use of ultrasound, fathers are able to visualize the developing fetus. During the second trimester, a father is able to make contact with his unborn child as he places his hand on his partner's abdomen and feels the life and movement within. For many men, this is a time of great joy, as the prospect of fatherhood becomes more than abstract empathy with his partner's experiences. Investment in the new life begins to increase as the reality of the fetus becomes more concrete. These times can provide the basis for a new kind of intimacy for the expectant couple as they begin to talk about their plans and hopes for the child, share their feelings about the pregnancy and upcoming birth, and explore their feelings related to assuming responsibility for the care and protection of their child.

However, some men turn away from the mother during her pregnancy. They may find features of pregnancy repugnant. They may fear losing their place in the mother's affection. They may become depressed, feeling that they cannot live up to the expectations for caring for and supporting their partner and the child (Deater-Deckard, Pickering, Dunn, & Golding, 1998). A father's depression may, in turn, have a negative effect on the mother, leaving her depressed and aware that she is without the support she was expecting.

Rod Morata/The Image Bank/Getty Images

Fathers are becoming increasingly involved in supporting their partner's pregnancy and delivery. This support is both an important aspect of identification with the father role and a great emotional comfort to the mother.

In some circumstances, men think that the fetus and then the baby threaten their own position with the mother, and they feel resentful and competitive toward the woman and the unborn infant. This resentment may lead to violence. The incidence of intimate partner violence (IPV) is difficult to summarize, due to differences in sample size, measurement approaches, and the timing of the assessment in reported studies. However, the problem of IPV during pregnancy appears to be widespread. One study of a rural sample of U.S. women reported that 81 percent of prenatal patients at a family practice clinic reported some type of IPV during pregnancy; 28 percent reported physical IPV, and 20 percent reported sexual violence (Bailey, 2007). Many studies find higher rates of prematurity and low birth weight in infants born to women who were victims of IPV (Bailey, 2010).

A growing awareness of the challenges facing expectant fathers has led to the publication of an assortment of advice books and websites. Unfortunately many of these resources tend to focus on the instrumental roles of fathers: Keep your job, know how to assemble the crib, be ready to be the family photographer and IT expert, get the nursery painted, install the car seat, etc. Not enough attention is given to the psychosocial issues facing men as they approach the new role of fatherhood. These resources could do more to provide expectant fathers with reassurance and encouragement about their ability to form a close, loving relationship with their baby, and the best ways to support their partner during the months leading up to the birth, as well as during the post-partum period. Men may need guidance and support from others as they reflect on their own experiences of being parented. These early experiences may provide good models for their approach to fatherhood; but they may also need revision. Men may need to alter their approach to balancing work and family life in order to enact a fulfilling father role. And they may need guidance about how to express the tender, caring, and loving aspects of their role within the framework of their masculine identity.

Fathers' Involvement in Labor and Delivery

Trends in the United States have shifted dramatically toward greater involvement of fathers during labor and delivery (Reed, 2005). Expectant fathers often attend childbirth classes to learn to assist their partners during the delivery. The father's presence during labor and delivery is typically a great comfort to the pregnant woman. When the father is present, women tend to have shorter labors, report experiencing less pain, use less medication, and feel more positive about themselves and their childbirth experience. Many fathers also describe their participation in the birth as a peak experience. They feel they are most helpful to their wives during labor, and they find the birth experience to be extremely powerful (Nichols, 1993).

Birthing experiences are commonly set in the context of a medical environment in which fathers may be viewed as assistants, but they may also be viewed as getting in the way. Negative experiences for men during childbirth occur when they are unsure what their role is during the delivery or when hospital personnel treat them rudely, as a disruption, stereotype them as unable to manage the events of childbirth, or fail to provide them with the information they want during the labor and delivery process (Johnson, 2002). When there are complications during the birth process, or if the birth is performed with cesarean delivery, it is likely that the father will be asked to leave the birth setting, often left alone until the birthing process is complete. This can lead to emotional turmoil for the father, resulting in post-traumatic stress disorder or depression and doubts about the ability to comfort and care for his partner and his baby. Little attention is given to men's needs as they make a psychological transition to fatherhood. We do not know how negative experiences in childbirth may impact subsequent interactions between a man and his partner or his children.

— **CASE STUDY** A Father's Recollections About His Daughter's Birth —

The sentiments of frustration and joy are captured in this description of a father's experiences during labor and delivery. The text was taken from a bulletin board discussion about fathers' views of whether they should be present at their child's birth on Blacknet.com, a place for dialogue and communication within the Black community of the United Kingdom.

Gonna remenise about when my first child was born, I remember being dragged out of work on a Wednesday am because my then wife had gone into labour. Someone however forgot to inform me that women needed to dialate. geeez.

So after rushing to Guys hospital I'm told Baby not ready. Anyway I'm waiting for said wife to get big enough so to speak. All flippin day, All day man watching the paint dry.

I was like Donkey in Shrek 2 'Are we there yet?' every five minutes, then night falls I think ok, maybe it will be a night birth. Oh nooo, nooo such luck.

So here am i holding my wifes hand, or was that her squeezing the blood out of my hand. hmmm yes that was it. I'm giving the '*i'm in control mans*' talk you know '*come on darling its ok, breath breath*' My girl is in full contractions now about 20 mins apart. So the top half of me is trying to be firm and calm, the bottom half is trying hard not to piss mi pants.

Then the nurse mentioned Epidural, oh my days I know i nearly passed out at the sight of the needle going into the spinal column, all the while that wretch is screaming blue murder in the next room. '*get it out*'.

Anyway after waiting ALL day (do I still sound vex?) and ALL night with a hardback chair for a bed, you know I'm happy right?… next thing I know doctor come in approx 8:40 am ish. '*ok lets do it*'. Next thing I know they pull out these stirrups out of nowhere and got my wife with both legs in the air like she's riding an invisable horse whilst lying on her back.

Then a whole heap of student doctors and nurses come into the room, and I mean a whole heap. So here's the wife with legs up in the air, fanny out of door, and all these strangers peering right up it. Now you know man is about to cuss right.

Anyway before I could get into it, baby starts to be delivered and out she pops, 9 am in the morning. she pops out. can't describe how i felt but it was as close to perfection as i will ever get. bonded with her and we've been close not matter what 21 years later.

Source: Kunjufu, (2004).

CASE ANALYSIS Using What You Know

1. Given all the stress of the situation, what might account for the very positive feelings reported by Kunjufu at the moment of birth?
2. Summarize the different roles that men can play during the childbirth process. What roles is Kunjufu playing?
3. How does the case illustrate reasons why some men might not want to be present during labor and delivery?
4. Assess how hospital personnel may influence the experiences of fathers during childbirth.
5. Explain how childbirth preparation classes might influence the experiences of fathers during childbirth.

The Impact of the Pregnant Woman on the Fetus

Among the factors that influence the fetus's development are the mother's age, use of drugs during pregnancy and delivery, exposure to environmental toxins, maternal depression, infections encountered during pregnancy, diet, and stress. The quality of a pregnant woman's physical and emotional health before and during pregnancy are linked to her own knowledge about, and preparation for, pregnancy as well as to her culture's attitudes and practices associated with childbearing. One of the most harmful influences of the psychosocial environment on fetal development is poverty. Embedded in the conditions of poverty are many of the individual factors mentioned above that are associated with suboptimal prenatal development.

The Impact of Poverty

Perhaps the most powerful psychosocial factor that influences the life chances of the developing fetus is poverty (Lipina & Colombo, 2009). Women living in poverty are likely to experience the cumulative effects of many of the factors associated with infant mortality and developmental vulnerabilities. Poverty is directly linked to poor prenatal care. Women who live in poverty are likely to begin having babies at an earlier age and to have repeated pregnancies into their later adult years—practices that are associated with low birth weight. Women who have had little education are less likely to be aware of the risks of smoking, alcohol, and drug use for their babies and are more likely to use or abuse these substances. Women living in poverty are less likely to have been vaccinated against some of the infectious diseases (e.g., rubella) that can harm the developing fetus. Poverty is linked with food insecurity; lack of safe, affordable housing; lack of health insurance; higher instances of infection; and higher rates of diabetes and cardiovascular disease, which are all linked to the infant's low birth weight and physical vulnerability (Burgard & King, 2015; MacDonald & Seshia, 2016).

Many of the risks that face infants born to women who live in poverty are preventable. One of the Millennium Development Goals established under the auspices of the United Nations was to reduce global maternal mortality rates 75 percent by the year 2015. A key element in achieving this goal was to dramatically increase the percentage of births attended by skilled medical personnel. Impoverished and rural women are currently far less likely than their wealthier urban counterparts to receive skilled care during childbirth. Inequality in access to skilled care between urban and rural women is especially notable in Sub-Saharan Africa where wealthier women are three times more likely to deliver with the assistance of skilled birth professionals than the poorest women. While the Millennium Goal was not achieved, significant progress was made. By 2015, the maternal mortality rate was reduced by 45 percent (United Nations, 2012, 2015).

A well-organized, accessible system of regional medical care facilities combined with an effective educational program on pregnancy and nutritional support can significantly improve the health and vigor of babies born to women in poverty. One of the central elements in delivering effective prenatal and continuing services to women in poverty is the establishment of a caring relationship between the woman and the health care provider. This caring relationship provides emotional support to the woman, encouraging her to feel valued as a client, as a mother, and as an adult in the community (Barnard & Morisset, 1995; Massey, Rising, & Ickovics, 2005).

Comprehensive prenatal care programs can improve birth outcomes even in a high-risk population. Delivery of coordinated care involves more than providing prenatal checkups and information about health care during pregnancy. It recognizes the complex challenges that face women in poverty, including violence, hazardous living conditions, poor quality services, and unstable or disruptive social relationships. Effective interventions must include nonmedical support services, such as making sure the woman has access to food stamps; is part of the Women, Infants, and Children (WIC) food program; has the transportation needed for prenatal and postnatal health care appointments; and receives housing assistance or job training as necessary (California Department of Public Health, 2016; McAllister & Boyle, 1998).

Living in a high-poverty neighborhood has been associated with poor pregnancy outcomes. However, disrupting a pregnant woman's housing arrangements, for example, by closing or dismantling a public housing project and forcing women to relocate, has also been found to increase the risk for having preterm, low-birth-weight babies (Kramer, Waller, Dunlop, & Hogue, 2012). The life chances and quality of survival of infants born in poverty are a reflection of the value that a society places on social justice.

Mother's Age

The capacity for childbearing begins about 1 to 1½ years after menarche (the beginning of regular menstrual periods) and normally ends at the climacteric, or menopause (the ending of regular menstrual periods, usually between the ages of 48 and 55). Thus, a woman is potentially fertile for 35–40 years of her life. Pregnancy and childbirth can occur at various times during this period. The effects of childbirth on the physical and psychological well-being of a mother vary with her age and emotional commitment to the mother role. Similarly, these factors also contribute significantly to the survival and well-being of her infant. In later chapters, we will discuss the psychosocial consequences of childbearing for adolescents and adults. Here we point out the birth outcomes and risks to mothers and infants that are associated with the age of the mother during pregnancy.

Women between the ages of 16 and 35 tend to provide a better uterine environment for the developing fetus and to give birth with fewer complications than do women under 16 or over 35. Particularly when it is their first pregnancy, women over 35 are likely to have a longer labor than younger women, and the labor is more likely to result in the death of either the infant or the mother. As expected, the two groups with the highest probability of giving birth to premature babies are women over 35 and those under 16 (Behrman & Butler, 2007). In an analysis of over 180,000 deliveries, the risk of having a preterm delivery increased with age for women living in poor neighborhoods, African American women, and women who smoked (Holzman et al., 2009).

Mothers under 16 tend to receive less adequate prenatal care and to be less biologically mature. Young mothers are likely to engage in other high-risk behaviors, including alcohol and drug use, that have negative consequences for fetal development. In addition, adolescent mothers are more likely than older mothers to be exposed to violence in their communities, homes, and in the context of intimate relationships, thus increasing their level of stress and an associated increased use of tobacco, alcohol, drugs, and antidepressants, all of which can have negative consequences for the developing fetus (Kennedy, 2006). As a result of these interacting factors, premature children of teenage mothers are more likely than those of older mothers to have neurological defects that will influence their coping capacities. Evidence suggests that good medical care, nutrition, and social support improve the childbirth experiences of adolescent mothers who are over 16. However, the physical immaturity of those under 16 puts the mother and infant at greater risk even with adequate medical and social supports (Behrman & Butler, 2007).

A primary risk for infants of mothers who are over 40 is Down syndrome. It is hypothesized that the relatively high incidence of Down syndrome in babies born to older women is the result, in part, of deteriorating ova. However, older women are also likely to have male partners who are their age or older. Even though new sperm are produced daily, some evidence suggests that among older men, the rate of genetically defective sperm increases. Thus, aging in one or both partners may contribute to the increased incidence of Down syndrome in babies born to older women. These explanations are not entirely satisfactory, however, because older women who have had multiple births are not as likely to have a baby with Down syndrome as are women who have their first child at an older age. Moreover, many babies with Down syndrome are born to women who are under 35. It is likely that in some cases, Down syndrome is a result of errors that occur during cell division and that in others, it is a result of a genetically transmitted condition (National Down Syndrome Society, 2013).

FIGURE 4.9 ▶ shows the rate of live births to women in the age range from 10 to 49 between 1960 and 2013. Overall, women are somewhat older today at the time of their first birth (Mean=26.0 years) than was the case in the past. With the exception of the very youngest and the very oldest women, the birth rate dropped substantially from 1960 to 1980. Current trends show a shift from the 1960s, when the highest birth rate was among women ages 20–24, to the present when the highest rate was among women 25–29. In comparison to the 1980s, the current trend shows an increase in childbearing for women in their 30s. Although there is a lot of concern about risks associated with teen pregnancy, the birth rate for the very youngest group (ages 10–14) is comparatively low, and the birth rate for those ages 15–19 has dropped notably since the 1990s (Martin et al., 2015) .

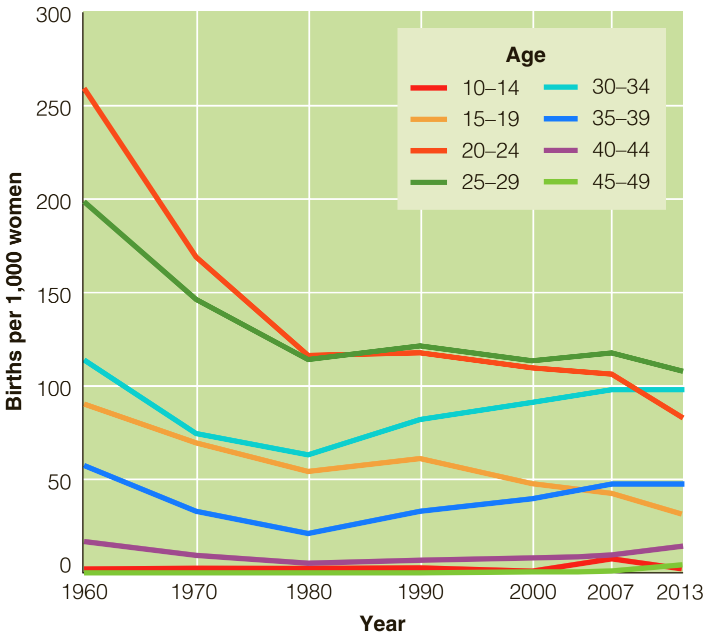

FIGURE 4.9 ▶ LIVE BIRTHRATES BY AGE OF MOTHER, 1960–2013

Maternal Drug Use

The range of drugs used by pregnant women is enormous. Iron, diuretics, antibiotics, hormones, tranquilizers, appetite suppressants, and other drugs are prescribed for or are purchased over-the-counter by pregnant women. Furthermore, women influence the fetal environment through their voluntary use of such drugs as alcohol, nicotine, caffeine, marijuana, cocaine, and other narcotics. Studies of the effects of specific drugs on fetal growth suggest that many drugs ingested by pregnant women are in fact metabolized in the placenta and transmitted to the fetus. Furthermore, although the impact of a specific dosage of a drug on the pregnant woman may be minimal, the impact on the fetus may be quite dramatic.

Male-mediated effects of drugs on fetal development are also documented but less well publicized. Drug abuse among men may produce abnormalities of the sperm that can account for birth defects in their offspring. Current studies are examining the possibility that addictive drug use by men and women prior to conception can have deleterious effects on the physical and behavioral development of offspring through the formation of epigenetic marks, even if these drugs are not used during the prenatal period (Pollard, 2000; Vassoler, Byrnes, & Pierce, 2014).

In reviewing the following sections about the impact of drugs on fetal development, three principles must be considered:

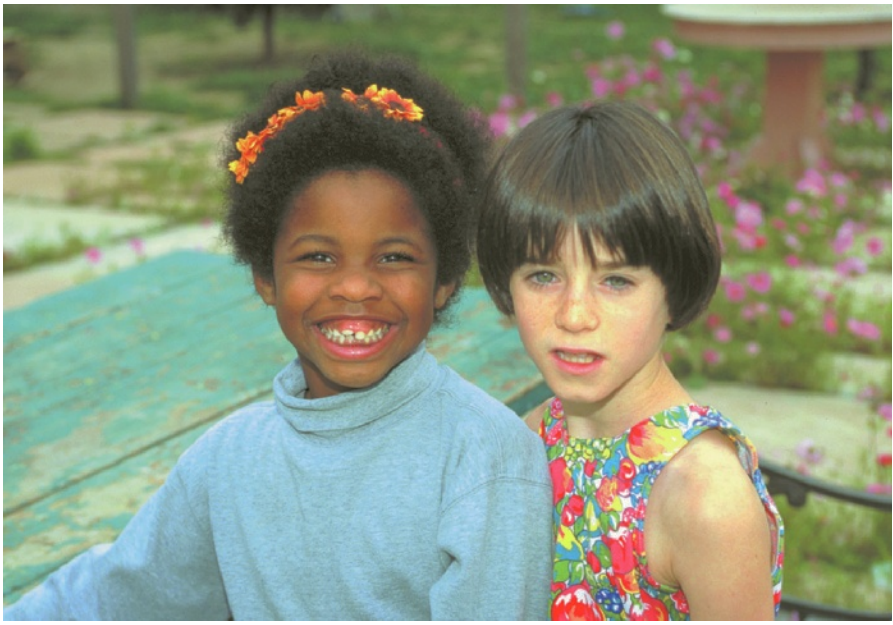
1. Evidence suggests that genetic predisposition may make some developing fetuses more vulnerable than others to the negative effects of certain drugs or toxins. Data on this genetic variability were derived from animal studies because animals are more likely to have large litters of offspring, some of which show greater resilience to the presence of prenatal teratogens than others (O'Rahilly & Muller, 2001).
2. Most teratogens do not have an all-or-none impact on the central nervous system. The consequence to the fetus of exposure to teratogens varies by the *dosage*, *duration*, and *timing* of exposure. A dosage that might be acceptable for the pregnant woman might be harmful to the developing fetus.
3. Research is sparse on the ways that specific medications are metabolized during pregnancy. Because of physiological changes during pregnancy, some medications may be metabolized so quickly that they do not treat the condition for which they were prescribed. In an effort to avoid harming the pregnant woman or the fetus, some serious conditions such as asthma or depression may be left untreated, thereby placing the pregnant woman and the fetus at risk for additional complications (Lyerly, Little, & Faden, 2009).

Nicotine. Smoking cigarettes is one of the most common, preventable causes of reduced fertility, conception delay, and negative birth outcomes (Centers for Disease Control and Prevention, 2012b). Women who smoke are at greater risk for miscarriages, stillbirths, preterm deliveries, low-birth-weight babies, and infant mortality. Children born to mothers who smoke are at increased risk for cleft lip and cleft palate, ear infections, and respiratory diseases, including asthma. Neurological examinations of babies exposed to nicotine during the prenatal period showed decreased levels of arousal and responsiveness at 9 and 30 days after birth. Infants of smokers have a three to four times greater risk of SIDS before 2 months of age. Although there is clearly a benefit to stopping smoking before pregnancy, research suggests that stopping smoking during pregnancy can also be associated with reduced health risks to the newborn.

Alcohol. The evidence is conclusive that alcohol is a teratogen. Prenatal exposure to alcohol can disrupt brain development, interfere with cell development and organization, and modify the production of neurotransmitters, which are critical to the maturation of the central nervous system (Sokol, Delaney-Black, & Nordsstrom, 2003). The complex impact of alcohol on fetal development has been given the name **fetal alcohol spectrum disorders** (Centers for Disease Control and Prevention, 2015d). Fetal alcohol spectrum disorders (FASDs) is an umbrella term for the range of effects that can occur in an individual whose mother drank alcohol during pregnancy. These effects include physical, mental, behavioral, and learning disabilities with possible lifelong implications. FASDs include **fetal alcohol syndrome (FAS)**, as well as other conditions in which individuals have some, but not all, of the clinical signs, which include abnormal facial features, growth deficiencies, and central nervous system (CNS) problems.

Damage to brain structures by alcohol can be detected through changes in fetal habituation at 35 weeks of gestational age (Hepper, Doman, & Lynch, 2012). The impact of FASD may become more notable as children reach the elementary and middle school grades as they face more challenging academic tasks. The compromised CNS may result in problems with learning, memory, attention span, communication, vision, hearing, or a combination of these. These problems often lead to difficulties in school and problems getting along with others. Individuals who were diagnosed with FAS in infancy continue to be at greater risk for health and mental health problems well into adulthood (Popova, Lange, Burd, & Rehm, 2012).

FAS is a permanent condition. At a rate of 0.2 to 1.5 infants affected per 1,000 live births, fetal alcohol syndrome is the greatest source of environmentally caused developmental disruption in the prenatal CNS. For every child born with FAS, an estimated three more children are born who suffer some of the neurological complications associated with fetal exposure to alcohol (Centers for Disease Control and Prevention, 2015d). Estimates of the costs associated with the educational, health care, and behavioral supports for people with FASDs are in the billions of dollars. The Centers for Disease Control and Prevention has a valuable website about FASDs that provides detailed information about diagnosis, treatment, statistics, research articles, and educational tools: http://www.cdc.gov/ncbddd/fasd/index.html.



David Young-Wolff/PhotoEdit

Both of these children show the facial characteristics of fetal alcohol syndrome: eyes widespread, with an epicanthic fold; short nose; small midface; and thin upper lip.

We emphasize the risks associated with prenatal exposure to alcohol because it is so widely used in American society and because even what many adults perceive to be a safe or socially acceptable amount of alcohol during pregnancy can have a negative effect on the fetus. In a national survey of pregnant women, 1 in 10 reported any alcohol use and 1 in 33 reported binge drinking in the past 30 days (Centers for Disease Control and Prevention, 2015d). According to the National Institute on Alcohol Abuse and Alcoholism, "there is no known safe amount of alcohol to drink while pregnant. Studies show that even drinking small amounts of alcohol during pregnancy may affect fetal brain development" (NIAA, 2011). In 2005, the U.S. Surgeon General advised all women who are pregnant or trying to get pregnant to abstain from alcohol consumption in order to prevent fetal exposure to alcohol. Because of discoveries that even minimal alcohol consumption could result in some disruption in fetal development, the old advice of limiting one's alcohol consumption during pregnancy has been revised. In order to prevent any possible damaging effects of alcohol, the advice is to abstain from alcohol consumption entirely (Centers for Disease Control and Prevention, 2015d).

Narcotics. The use of narcotics, especially heroin and cocaine, as well as methadone (a drug used in the treatment of heroin addiction), has been linked to increased risks of birth defects, low birth weight, and higher rates of infant mortality. Cocaine has both an indirect and direct impact on fetal development. Complications of pregnancy and fetal development occur when a pregnant woman uses cocaine. Cocaine increases a woman's blood pressure and constricts blood vessels at the site where the uterus and the placenta are connected, resulting in a decrease in the oxygen supply to the fetus, which can lead to fetal anomalies. What is more, cocaine crosses the placenta, resulting in direct effects on fetal blood circulation, with potential consequences for cell death in the brain or intestines, cardiac disorders, and other disruptions in organ development and function (Tantibanchachai & Zhang, 2015).

Shortly after birth, infants who have been exposed prenatally to opiates, cocaine, and methadone show evidence neonatal abstinence syndrome, otherwise referred to as withdrawal. This syndrome can include symptoms such as neurological disorganization, fever, sleep disturbances, feeding problems, muscle spasms, and tremors (Bard et al., 2000; Farid, Dunlop, Tait, & Hulse, 2008).

Prenatal cocaine exposure has been linked to cortisol reactivity. Cortisol is a hormone that contributes to a person's ability to manage and regulate the responses to the stressors of daily life. Babies who were exposed to cocaine prenatally were observed at 7 months of age. They had elevated cortisol levels, which leads to greater reactivity to stress, and disruptions in the ability to self-regulate. The disruptive consequences of cocaine exposure were more serious when the caregiving situation was unstable, suggesting that the infants who were physiologically predisposed to having difficulties in managing arousal and stress suffered even further when they were not able to rely on a consistent context of care (Eiden, Veira, & Granger, 2009). Longer range studies found that some children who were exposed to addictive drugs in the prenatal period continued to show problems with fine motor coordination, had difficulty focusing and sustaining their attention, and, perhaps as a result, had more school adjustment problems (Ben-Dat Fisher et al., 2007). In a study that followed children from birth to mid-adolescence, prenatal exposure to cocaine was related to poorer perceptual organization IQ, visual–spatial information processing, attention, language, executive function, and behavior regulation through early adolescence (Singer et al., 2015).

Of course, it is difficult to separate the direct prenatal effects of these drugs on the nervous system from the effects of other negative teratogens on fetal development, such as alcohol and nicotine use, maternal malnutrition, or sexually transmitted diseases. Long-term consequences of prenatal exposure to teratogens are also confounded with post-natal conditions associated with being parented by a drug-abusing mother, or exposure to a violent or neglectful home environment (National Institute on Drug Abuse, 2010). One study focused on the caregiving environment of 2-year-old children who had been prenatally exposed to cocaine. Those who were in nonparental caregiving environments were doing much better at age 2 with respect to physical development, cognitive and language skills, and social and emotional functioning than those who continued in the care of their cocaine-using birth mothers (Brown et al., 2004a).

In a similar study, children who were exposed prenatally to methamphetamine were evaluated again at age 5. The children who had been prenatally exposed to methamphetamine were more than twice as likely as a comparison group to have significant externalizing behavior problems (i.e., problems managing their impulses, including expressions of anger, harming others, and breaking things). Those children who continued living with their biological mothers had more behavioral problems than those similarly exposed who were separated from their biological mothers and placed in the hands of a calmer, responsive caregiver. The results of this research suggest that in addition to the direct harm of prenatal drug exposure, these babies are also more sensitive to the potentially disruptive impact of harsh, neglectful, or inconsistent care after birth (Twomey et al., 2013).

Should women who use illegal substances also be charged with child abuse or child endangerment? Currently, one state, Tennessee, has criminalized maternal substance abuse during pregnancy. Supreme courts in Alabama and South Carolina have found that drug use while pregnant is considered the criminal endangerment/abuse of a child. However, 18 states have altered their child welfare statues and guidelines so that prenatal drug use can be grounds for ending parental rights based on child abuse or endangerment. Moreover, 18 states require health care professionals to report any suspected prenatal drug use to the state child welfare agency. Four states require health professionals to do testing for drug use as well as reporting. Recognizing the neurobehavioral consequences of prenatal exposure to cocaine and other opiates, 19 states are funding drug treatment programs specifically for pregnant women (Guttmacher Institute, 2016).

Prescription Drugs. Some drugs are administered to women during pregnancy as part of the treatment of a medical or psychological condition. Some drugs are administered to help sustain the pregnancy. Studies examining the dose and timing of these drugs suggest that they can have temporary or long-term consequences for fetal development by altering the blood supply to the fetus, interfering with neurological development, and altering the functioning of the placenta, thereby restricting nutrition and growth. The effects of some kinds of drugs may persist long after birth, either by directly altering the CNS or by influencing the pattern of caregiver–infant interactions. In some cases, women who have had certain drugs prescribed for pain, anxiety, sleep disturbances, or hyperactivity become dependent upon these medications and take them in greater doses, or beyond the time for which they were prescribed. Abuse of prescription drugs is among the causes of low birth weight and fetal abnormalities. The American Pregnancy Association provides information about potentially harmful prescription drugs and guidelines to determine if one is abusing these drugs (American Pregnancy Association, 2015b).

A recent controversy focuses on decisions about the treatment of depression among pregnant women. Estimates of the prevalence of depression among pregnant women suggest that about 6 percent experience major depression; and 16.6 percent experience minor depression. Whereas the risk of major depression is about the same for pregnant and nonpregnant women, the risk of minor depression is substantially greater for pregnant women (Ashley et al., 2015). What is more, 30 percent to 40 percent of women who have a history of major depression prior to pregnancy experience a relapse during the perinatal period (Dimidjian et al., 2016).

Antidepressant medications are prescribed to help relieve symptoms of depression. The hormonal changes of pregnancy can make it more difficult to cope with depressive thoughts and emotions. The decision to stop taking these medications during pregnancy could lead to health risk behaviors including an increase in smoking or alcohol use, poor eating or sleeping patterns, or a general indifference to one's health. On the other hand, there are some risks associated with certain antidepressant medications. For example, Paxil has been associated with an increased risk of fetal heart defects; certain other antidepressants have been linked to limiting fetal growth. Moreover, infants born to women who have been taking antidepressants during pregnancy have been found to show some withdrawal symptoms following birth. While the risks of many antidepressants are low, women and their health care providers have to consider how best to manage this situation (Mayo Clinic, 2015).

Caffeine. Caffeine freely crosses the placenta. It is commonly consumed in coffee and coffee-flavored ice creams, certain sodas, energy drinks, teas, and chocolates. An estimated 200 foods and food products contain caffeine. Caffeine raises the heart rate and acts as a diuretic, resulting in loss of fluids and the possibility of dehydration. Heavy caffeine consumption—defined in one study as more than 300 milligrams, or roughly three cups of coffee per day—is associated with an increased risk of low birth weight, and there is a modest relationship to prematurity. Babies exposed to high doses of caffeine have been found to have a higher heart rate, more startles and tremors, and are more difficult to soothe (Howell, 2005).

The impact of caffeine on fetal development is not fully understood. Most medical and health sources suggest that pregnant women should be cautious in their intake of caffeine, limiting the amount to 200 mg per day. (An 8 oz. cup of coffee has about 95 mgs of caffeine.) In striving to limit caffeine, women need to check the content in drinks, foods, and over-the-counter and prescription medications, such as cough and cold products. This can be challenging. For example, the U.S. Food and Drug Administration does not require manufacturers of energy drinks to put the amount of caffeine in their products on the label. Some energy drinks have large amounts of caffeine as well as other ingredients that may be harmful to the developing fetus (March of Dimes, 2016; Mayo, 2014).

Environmental Toxins

Because of the large number of women in the workplace, including many who assume nontraditional work roles, concern about the hazards of work settings for fetal development continues to grow. It is difficult to assess the causal links between exposure to specific chemicals and their impact on reproductive health in humans. The levels of exposure to environmental toxins that may be considered safe or acceptable for adults may still have a negative impact on fetal development. What is more, it is difficult to control for the possible accumulation of toxins that might be present in a person's system due to workplace exposure, water, air, and diet. Current reports from the National Safety Council and the National Institute for Occupational Safety and Health identify a long list of agents that pose potential harm to reproductive health for women and men. Furthermore, childbearing women whose partners are exposed to these substances may suffer from secondary exposure that can have a harmful impact on the developing fetus (National Safety Council, 2013; *Science Daily*, 2005).

The workplace is not the only setting in which pregnant women may be exposed to environmental toxins. For example, mercury, used in the manufacture of a variety of products, finds its way into the air and then into oceans and waterways where it is ingested by fish. Large fish, like tuna and swordfish, eat the smaller fish, thereby accumulating greater concentrations of mercury. When these fish are eaten by humans, the mercury acts as a neurotoxin, harming the brain and nervous system. Exposure to mercury is especially harmful for fetal development due to its impact on brain development. Pregnant women who eat a lot of fish have to be particularly careful about the source of those fish and the amount they eat (National Resources Defense Council, 2013). All communities must be sensitive to the quality of their water, air, and soil. Each new generation depends on its predecessors for protection from environmental hazards.

Mother's Diet

The notion that no matter what a pregnant woman eats, the fetus will get what it needs for growth is simply not true. Providing adequate nutrition for fetal development requires both a balanced diet for the mother and the capacity to transform nutrients into a form that the fetus can ingest through the placenta (Tanner & Finn-Stevenson, 2002).

Because of ethical problems involved in experimentally modifying the diets of pregnant women, much of the research on the effects of maternal malnutrition on fetal development has been conducted with animal models, primarily rats. The impact of prenatal malnutrition on rats shows that when the mother is malnourished, fewer nutrients cross the placenta. The fetal brain receives comparatively more of the limited nutritional resources than the other organs; however, the central nervous system (CNS) is disrupted. The consequences, for those fetuses that survive, include delayed skeletal development, impaired reflexes, and cognitive deficits (Galler & Tonkiss, 1998; Lukas & Campbell, 2000).

The impact of prenatal malnutrition on human development depends on its timing, severity, and the particular nutrients that are absent from the mother's diet. Prenatal malnutrition has an immediate negative impact on fetal growth including the growth of organs, organ functions, and the CNS. Babies who experience prenatal malnutrition are likely to be small for their gestational age and are more likely to suffer birth complications.

Prenatal malnutrition is also associated with longer term health and behavioral problems including learning disabilities, mental illness, and motor impairments. Studies of children born during a severe food shortage in the Dutch Hunger Winter of 1944–45 found that these individuals had impaired glucose tolerance and a greater incidence of coronary heart disease and elevated blood pressure in adulthood (Langley-Evans, 2006; Neugebauer, Hoek, & Susser, 1999).

One of the nutrients of grave concern because of its role in the maturation of the CNS is iron. The brain uses iron to help support the speed of neural firing. Iron deficiency is a widespread nutrient disorder, with an estimated 20 percent to 25 percent of babies worldwide suffering from **iron deficiency anemia**. During pregnancy, iron deficiency is common since a woman's blood has to serve her own increased blood volume as well as be a source of hemoglobin for the maturing fetus. Babies who have severe iron deficiencies test lower in motor and cognitive development and show evidence of fearfulness, fatigue, and wariness. Even with postnatal iron-enriched treatment, these behavioral consequences have been found to persist (Georgieff, 2008; National Research Council and Institute of Medicine, 2000).

Programs targeted at pregnant women who are at risk for malnutrition often supplement the diet with foods that are rich in protein and high in calories. These supplements have been found to be effective in reducing infant mortality, birth defects, and the number of babies born small for gestational age. In order for these interventions to be truly effective, they must be coupled with efforts to reduce the continued effects of poverty after birth. Children who are at risk for malnutrition are likely to experience more illness, lethargy, and withdrawal; delayed physical growth; and, in consequence, delayed intellectual growth. Some of these negative effects of malnutrition can be offset if infants are adequately nourished after birth (Tanner & Finn-Stevenson, 2002).

Pregnant women have to be especially careful about the preparation and safety of the foods they eat. During pregnancy, a woman's immune system may be weaker, and the immune system of the fetus is not fully developed. As a result, both the woman and the fetus may be especially vulnerable to bacteria, viruses, and parasites that can cause food-borne illnesses. Pregnant women are advised to avoid eating raw eggs and unpasteurized milk, juice, and cheese products, to thoroughly cook meats, and to thoroughly wash fruits and vegetables to prevent eating foods that may have come into contact with contaminants. The U.S. government has produced an informational website and guidelines about some of the potential risks of various foods to pregnant women and their unborn children (Foodsafety.gov, 2016) (see FIGURE 4.10 ▶).

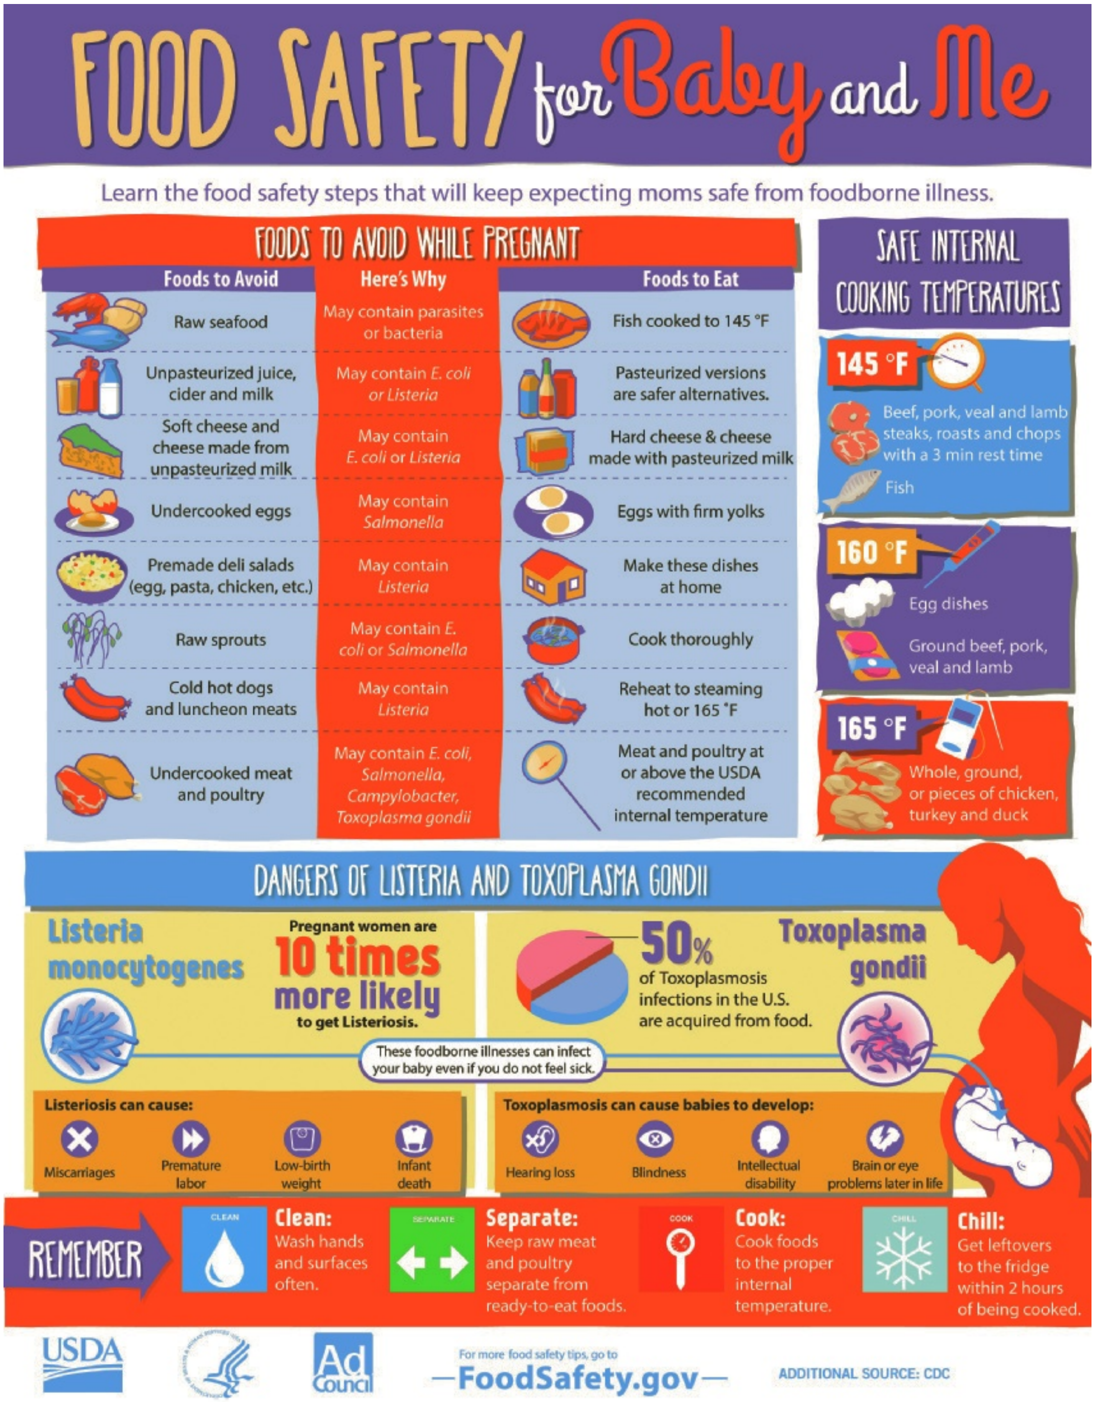
Stress and Fetal Development

Strong emotional reactions in mothers—such as prolonged anxiety or depression—may influence the fetal environment directly through the maternal hormones that cross the placental barrier. A review of existing literature suggests that among humans, prenatal stress is associated with higher rates of spontaneous abortion, preterm labor and delivery, and growth delay among babies (Mulder et al., 2002). Stress-related changes in endocrine levels during pregnancy are associated with motor development, cognitive development, and immune functioning in babies. Research is focusing on ways in which stress- induced physiological changes in the mother might influence fetal growth and nervous system development (DiPietro, 2004, 2012; Field et al., 2003).

What are the sources of stress for pregnant women that can have an impact on the developing fetus? Studies have explored the role of women's exposure to psychosocial stress and racism on birth outcomes. Prenatal anxiety is higher among those women who have a less positive outlook about their pregnancy and who are undergoing a large number of challenging life events during pregnancy. In a comparison of European American, African American, and Latina women, the sources of prenatal anxiety were different for women of the different racial/ethnic groups. Income inadequacy was the primary source of prenatal anxiety for European American women. For African American women, both childhood and current exposure to racism was significantly related to pregnancy stress. For Latinas, a sense of mastery and support from the baby's father were factors that reduced levels of pregnancy stress (Dominguez et al., 2008; Gurung et al., 2005).

Another source of stress is related to a woman's working conditions. Although it is generally positive for women to be employed and to have work-related income, work-related strain can have a negative impact on fetal development. The following work conditions were identified as especially stressful: working 32 hours a week or more early in their pregnancy; a demanding work pace, including time pressures and expectations to do multiple tasks as once; and physically demanding, strenuous work. These work conditions were associated with greater risk for having low-birth-weight babies or babies who were small for their gestational age (Vrijkotte, van der Wal, van Eijsden, & Bonsel, 2009).

A mother's emotional state during pregnancy has an impact beyond the events of childbirth. Women who experience severe anxiety or depression during pregnancy are more likely to continue feeling depressed after giving birth and are more likely to have additional depressive symptoms in the 5 years following childbirth. Clinicians who focus on the causes and treatment of



FOOD SAFETY for Baby and Me
Learn the food safety steps that will keep expecting moms safe from foodborne illness.
FOODS TO AVOID WHILE PREGNANT
Foods to Avoid
Here's Why
Foods to Eat
Raw seafood
May contain parasites or bacteria
Fish cooked to 145 °F
Unpasteurized juice, cider and milk
May contain E. coli or Listeria
Pasteurized versions are safer alternatives.
Soft cheese and cheese made from unpasteurized milk
May contain E. coli or Listeria
Hard cheese & cheese made with pasteurized milk
Undercooked eggs
May contain Salmonella
Eggs with firm yolks
Premade deli salads (egg, pasta, chicken, etc.)
May contain Listeria
Make these dishes at home
Raw sprouts
May contain E. coli or Salmonella
Cook thoroughly
Cold hot dogs and luncheon meats
May contain Listeria
Reheat to steaming hot or 165 °F
Undercooked meat and poultry
May contain E. coli, Salmonella, Campylobacter, Toxoplasma gondii
Meat and poultry at or above the USDA recommended internal temperature
SAFE INTERNAL COOKING TEMPERATURES
145 °F
Beef, pork, veal and lamb steaks, roasts and chops with a 3 min rest time
Fish
160 °F
Egg dishes
Ground beef, pork, veal and lamb
165 °F
Whole, ground, or pieces of chicken, turkey and duck
DANGERS OF LISTERIA AND TOXOPLASMA GONDII
Listeria monocytogenes
Pregnant women are 10 times more likely to get Listeriosis.
50% of Toxoplasmosis infections in the U.S. are acquired from food.
Toxoplasma gondii
These foodborne illnesses can infect your baby even if you do not feel sick.
Listeriosis can cause:
Miscarriages
Premature labor
Low-birth weight
Infant death
Toxoplasmosis can cause babies to develop:
Hearing loss
Blindness
Intellectual disability
Brain or eye problems later in life
REMEMBER
CLEAN
Clean: Wash hands and surfaces often.
SEPARATE
Separate: Keep raw meat and poultry separate from ready-to-eat foods.
COOK
Cook: Cook foods to the proper internal temperature.
CHILL
Chill: Get leftovers to the fridge within 2 hours of being cooked.

depression in women emphasize that the period of pregnancy and childbirth should be a time for preventive intervention (Le, Munoz, Ippen, & Stoddard, 2003).

Summary

The many risk factors we have reviewed, including maternal age, exposure to drugs and environmental toxins, exposure to medications, inadequate nutritional resources, and stress, can occur singly or in combination. The greater the number of risk factors the fetus encounters, the greater the chance for disruption in neurological and behavioral development. As suggested by the model for the differential effect of the childrearing environment presented earlier in the chapter (Figure 4.6), psychosocial processes can contribute to growth and new resources for coping or to disruption and limitations on coping. Within the prenatal environment, a child's genetic potential may encounter a supportive, healthy, optimizing environment or an environment in which one or more conditions place fetal development at risk. For infants who carry the genetic markers for anomalies, the expression of these conditions may be less severe when fetal development has taken place in a healthy, fully resourced uterine environment. In contrast, even infants who would otherwise be healthy may suffer long-term negative consequences when they are exposed to a combination of teratogens and disruptive uterine conditions.

FURTHER REFLECTION *Based on what you have read, what is your view about whether pregnant women should work? Describe what you consider to be the best work environments for a pregnant woman and her partner, and the least desirable environments.*

The central nervous system is a work in progress that matures throughout pregnancy. As you review the sections above, make a list of the many ways that the baby's CNS may be influenced by the fetal environment.

The Cultural Context of Pregnancy and Childbirth

OBJECTIVE 6 Examine the impact of culture on pregnancy and childbirth.

> Julan is a Hmong, now living in Australia. She has just had a baby, and she and her family are preparing for the soul-calling ceremony on the third day after the baby's birth. Once completed, she will feel that she has done what is needed to protect the baby and link it to its living as well as its supernatural world. The Hmong believe that each of us has three souls—one that enters the body when the infant is conceived, one that enters as the baby takes its first breath during childbirth, and one that enters on the third day after birth. The soul-calling ceremony secures these souls in the infant's body and thus ensures the baby's well-being. (Rice, 2000)

Cultures differ in the ways they "script" pregnancy and birth. The beliefs, values, and guidelines for behavior regarding pregnancy and childbirth have been referred to as the **birth culture** (Gross & Pattison, 2007). The decision to have a child, the social and physical experiences of pregnancy, the particular style of help that is available for the delivery of the child, and the care and attitudes toward mother, father, and baby after delivery are all components of the birth culture. Not everyone in a cultural group adheres to the full script of the birth culture, but at the very least, these guidelines are part of the mythology or lore that surfaces as a woman and her partner experience the events of pregnancy. Within larger countries, it is common to find a diversity of cultural groups, each of which has its own birth culture. This requires new levels of cultural competence and sensitivity among health care providers in order to provide optimal prenatal and childbirth services for a culturally diverse population.

Reactions to Pregnancy

Many cultures share the assumption that the behavior of expectant parents will influence the developing fetus and the ease or difficulty of childbirth. Of the 64 cultures studied by Ford (1945), 42 prescribed certain behaviors for expectant parents and prohibited others. Many such restrictions were dietary.

In many Asian, Mediterranean, and Central and South American cultures, pregnancy is believed to be affected by the balance of hot and cold foods in a woman's diet. For example, during pregnancy, Vietnamese women are likely to follow dietary practices that permit "hot" foods such as ginger and black pepper in the first trimester and avoid "cold" foods such as lemon, melon, or pineapple. Pregnant Vietnamese women often use traditional plant and herbal medicines to support their health and the health of their babies (Queensland Government, 2012).

A culture's view of pregnancy determines the kinds and severity of the symptoms associated with it, the types of treatment or medical assistance sought during pregnancy, and the degree to which pregnancy is responded to as a life stressor. Attitudes toward pregnant women can be characterized along two dimensions: (1) **solicitude versus shame** and (2) **adequacy versus vulnerability** (Mead & Newton, 1967). A syndrome of fathers' reactions to a wife's pregnancy, called couvade, is discussed in the following **Human Development and Diversity** box Couvade.

Solicitude Versus Shame

Solicitude toward the pregnant woman is shown in the care, interest, and help of others. For example, when Chinese women are pregnant, they are likely to take on a "sick role" in which they rely heavily on others for help. This role is expected; other members of the family offer comfort and encourage her to rely on older relatives at this time (Queensland Government, 2012). Earlier in the chapter we noted the low incidence of birth complications and low birth weight among Mexican immigrant women, despite their limited economic resources. Their positive childbirth experiences are attributed in large part to the value placed on family relations and the support shown to pregnant women by their kinship network. The Korean beliefs called **Taegyo** assume that the fetus is able to feel what the mother feels. As a result, a very detailed set of guidelines were established that encourage the creation of a peaceful, comfortable surrounding for pregnant women as well as recommendations for the woman's diet, activities, and exposure to positive, beautiful stories, songs, and paintings (Kim, 2002).

At the other end of this spectrum are the cultures that convey shame through their practices. They keep pregnancy a secret as long as possible. This custom may stem from a fear that damage will come to the fetus through supernatural demons or from shyness about the sexual implications of pregnancy.

Societies that demonstrate solicitude increase the care given to the pregnant woman and fetus. These attitudes emphasize the importance of birth as a mechanism for replenishing the group, and additional resources are likely to be provided to the pregnant woman. By keeping the pregnancy a secret, cultures that instill a sense of shame in the woman do not promote the health of the mother or the fetus and may not encourage couples to have children.

Couvade

Couvade, or sympathetic pregnancy, is a syndrome in which otherwise healthy men whose partners are pregnant experience pregnancy-related symptoms (Nippldt, 2016). Couvade has been observed in two forms. The first is a deliberate enactment of rituals expected for men whose partners are pregnant. In the formal cultural practice of couvade, the expectant father takes to his bed and observes very specific taboos during the period shortly before birth. Among the Arapesh of New Guinea, childbearing is believed to place as heavy a burden and drain of energy on the father as on the mother. Some cultures believe that by following the ritual of couvade, fathers distract the attention of evil spirits, so that the mother and baby can go through the childbirth transition more safely (Helman, 2007).

The second form of couvade is a more unconscious emergence of pregnancy-related symptoms (Bauer, 2014; Brennan, Ayers, Marshall-Lucette, & Ahmed, 2007; Klein, 1991).

> "My husband is experiencing constipation, gas, bloating, irritability, and nausea right along with me," says one BabyCenter mom-to-be. And dad Mathew Erickson admits, "During my wife's pregnancy, I gained 15 pounds and had severe swelling in my hands." (Lack, 2016)

One source reported that 31 percent of expectant Australian fathers experienced eight or more physical and psychological couvade symptoms, such as general fatigue, weight gain, food cravings, stomach cramps, nausea, dizziness, or backache. Symptoms often begin toward the end of the first trimester, are noticeable again toward the end of pregnancy, and end with childbirth (Brennan, 2010).

> One study participant indicated that a number of his symptoms occurred concurrently with his partner's pregnancy most particularly, stomach pain/cramps, increased appetite and weight gain.
>
> "Stomach pains were not so much pains as weird movements in my stomach that I had never felt before. I felt much hungrier and have just started to work on losing the weight I put on whilst my wife was pregnant. . . . have not put on this much weight before. I have put an average of 5 kilos more on than usual." (Brennan, 2010)

Trethowan (1972), one of the first to document the nature and extent of couvade symptoms in the normal population, suggested that these physical symptoms are the product of a man's emotional ambivalence toward his wife during her pregnancy. The expectant father may experience empathy and identify with his wife's pregnant state. At the same time, he may experience some jealousy of his wife, resentment of the loss or potential loss of intimacy in their relationship, repulsion by his wife's physical appearance, or some envy of his wife's ability to bear a child. These psychological conflicts, many of which are probably unconscious or unexpressed, are amplified by an expectant father's conscious worries about the health and well-being of his wife and their baby. Contemporary ob-gyn physicians recognize the couvade syndrome and suspect that a combination of empathy and stress, each of which can be accompanied by unique hormonal changes, may account for some of the couvade symptoms (Lack, 2016).

Critical Thinking Questions

1. Investigate societies in which couvade is routinely practiced. What are some characteristics of these societies?
2. Evaluate the functions that might be served by couvade rituals.
3. Interpret why a woman's pregnancy may create conflict for her male partner.
4. In addition to the explanations for couvade symptoms presented in this box, what other explanations can you think of?
5. Explore the literature to see if there is any evidence of couvade symptoms for lesbian, gay, bisexual, or transsexual (LGBT) couples who are expecting a child.

Adequacy Versus Vulnerability

In many societies, pregnancy is a sign of sexual prowess and a means of access to social status. Some cultures do not arrange a wedding until after the woman has become pregnant. In a polygynous family—one in which a man has more than one wife—the pregnant wife receives the bulk of her husband's attention and may prevent her husband from taking an additional wife (Grandquist, 1950). Among Melanesian Fijians, the status of a married woman rises when she becomes pregnant. The community comes together to support Fijian women during pregnancy and in the months after childbirth, providing both emotional and material resources (Queensland Government, 2012).

The other end of this continuum is the view that *childmaking* is exhausting, pregnant women are vulnerable, and women grow more frail with each pregnancy. Among Samoans, many women believe that pregnancy is an illness. A lone pregnant woman is vulnerable to evil spirits and should avoid going out alone or being in the house alone. Samoan women may believe that a variety of practices, such as wearing earrings or floral arrangements around the neck, may result in disfiguring or harming the fetus (Queensland Government, 2012). Many cultures teach that during pregnancy, the woman and the fetus are more readily exposed to evil spirits. In several cultures, the forces of life and death are thought to be engaged in

In an effort to reduce infant and maternal mortality in Nepal, community volunteers visit women in the countryside to teach expectant mothers about safe practices. This is an example of an increasing effort toward solicitude and care in a developing nation.

a particularly intense competition for the mother and the fetus around the time of delivery.

Solicitude versus shame and adequacy versus vulnerability are two dimensions that create a matrix within which the birth culture of any society or subculture can be located. Within this framework, pregnancy may be viewed as a time of great rejoicing or a time for caution and privacy; a time for feeling sexually powerful or extremely vulnerable. One might describe the U.S. medical birth culture as being characterized by solicitude and vulnerability. Pregnant women are usually treated with increased concern and care and are often placed in a medical system that increases their sense of dependency. Attitudes in the workplace also contribute to the sense of vulnerability when pregnancy is viewed as incompatible with serious dedication to the job. In the workplace, women are likely to be devalued when they are pregnant, especially if they are engaged in jobs that are typically held by men (Hebl, King, Glick, Singletaary, & Kazama, 2007).

Reactions to Childbirth

Childbirth is an important event in most societies, marked by the presence of specially designated attendants, a specified location, and certain ceremonies and rituals intended to support the miraculous emergence of the newborn into the society (Dundes, 2003). In traditional societies, the delivery is usually attended by two or more assistants with specific assigned roles. They are usually women who have had children themselves and are respected members of their community. In Jamaica, the *nana*, or midwife, is one of the key figures in the village. She is called on to assist in many family crises. During pregnancy and childbirth, the nana provides assistance in the many rituals and taboos that mark the rebirth of the woman as a mother, and she usually cares for the mother and the infant until the ninth day after birth (MacCormack, 1994).

In most traditional cultures, childbirth takes place in a familiar setting, either at home or in a nearby birthing hut. If the birth takes place at home, a woman may be separated from others by a curtain for privacy, but she knows that her family members are close at hand. Women typically give birth standing, squatting, or sitting and reclining against something or someone. The Western birth custom of lying on one's back with one's feet propped up in the air has no counterpart in traditional birth cultures, nor are women expected to be moved from one setting or room to another during the phases of labor. That appears to be a ritual reserved for women in modern, industrialized societies. Views about the birth itself range from an extreme negative pole, where birth is seen as dirty and defiling, to an extreme positive pole, where it is seen as a personal achievement. The view of childbirth as a normal physical event is the midpoint on this continuum (Stone & Selin, 2009).

When birth is viewed as dirty, as it is by the Arapesh of New Guinea and the Kadu Gollas of India, the woman must go to an area away from the village to deliver her child. Many cultures, such as that of the ancient Hebrews, require extensive purification rituals after childbirth. Vietnamese villagers believe that mothers should not bathe or shampoo their hair for a month after giving birth so that the baby will not "fall apart," and that the new mother must not have sexual intercourse for 100 days (Stringfellow, 1978).

A slightly more positive orientation toward childbirth is to identify it as a sickness. This view causes a pregnant Cuna Indian woman to visit her medicine man for daily medication. The midpoint of this spectrum—what we might most appropriately describe as natural childbirth—is a setting in which the mother delivers her baby in the presence of many members of the community, without much expression of pain and with little magic or obstetrical mechanics. Clark and Howland (1978) described childbirth for Samoan women as follows:

> The process of labor is viewed by Samoan women as a necessary part of their role and a part of the life experience. Since the baby she is producing is highly valued by her culture, the mother's delivery is also commendable and therefore ego-satisfying. Pain relief for labor may well present the patient with a conflict. She obviously experiences pain as demonstrated by skeletal muscle response, tossing and turning, and fixed body positions, but her culture tells her that she does not need medication. It is the "spoiled" palagi [Caucasian] woman who needs pain-relieving drugs. Moreover,

> the culture clearly dictates that control is expected of a Samoan woman, and no overt expressions of pain are permissible. (p. 166)

At the most positive end of the scale, birth is seen as a proud achievement. Among the Ila of Northern Zimbabwe, women attending childbirth were observed to shout praises of the woman who had a baby. They all thanked her, saying, "I give thanks to you today that you have given birth to a child" (Mead & Newton, 1967, p. 174).

A similar sentiment is expressed in Marjorie Karmel's (1983) description of the Lamaze method of childbirth:

> From the moment I began to push, the atmosphere of the delivery room underwent a radical transformation. Where previously everyone had spoken in soft and moderate tones in deference to my state of concentration, now there was a wild encouraging cheering section, dedicated to spurring me on. I felt like a football star, headed for a touchdown. (pp. 93–94)

The American view of childbirth is evolving toward an emphasis on safety for mother and child and convenience for mothers and medical professionals. In comparison with the medical practices of the 1940s and 1950s, there is greater involvement of fathers or other birth coaches during labor and delivery and more immediate contact between newborns and their parents. There are more opportunities for the newborn baby to spend much of the day with the mother and for siblings to visit. Hospital stays are short—one or two days. Many hospitals have birth centers that provide a home-like environment where fewer technical interventions are used and the birth is attended by a midwife or obstetrical nursing team.

Couples are advised about the best way to promote the healthy development and safe delivery of their child as follows: (1) make early and regular visits to their obstetrician during the prenatal period; (2) attend childbirth classes; (3) observe recommendations for diet and use of drugs; and (4) avoid exposure to certain environmental hazards that may harm the fetus. In the United States, 99 percent of births take place in hospitals or hospital-affiliated centers, and 91 percent are attended by physicians (BabyCenter.com, 2007). Despite the fact that the overwhelming majority of women giving birth are healthy and could expect an uncomplicated birth, over half of women surveyed in 2006 experienced an induced labor or cesarean delivery, thereby exposing themselves and their babies to a variety of drugs and surgical interventions that bypass spontaneous labor (Declercq, Sakala, Corry, & Applebaum, 2006).

> I had a lot of pressure from the nursing staff to take Pitocin and to have an epidural. I felt like the birth experience was severely impacted by this pressure, as if the most important thing to the nurses was for me to have the baby quickly. My doctor is a big fan of induction which is not my cup of tea. (Childbirthconnection.org, 2007)

It is reasonable to speculate that events at the time of the birth influence a mother's feelings about herself and her parenting ability. Efforts by her community—especially family members, close friends, and health care professionals—to foster a woman's competence in, and control of, parenting and to express care and support for her seem to promote a woman's positive orientation toward herself and her mothering role. On the other hand, messages of social rejection, doubts about a woman's competence, and attempts to take away control or to isolate the mother from her infant or social support system may undermine the woman's self-esteem and interfere with her effectiveness as she approaches the demanding and exhausting task at hand (Dunkel-Schetter, 2009; Dunkel-Schetter, Sagrestano, Feldman, & Killingsworth, 1996).

Each country has a distinct approach to medical care during childbirth and the management of a birthing environment. These differences influence what a woman and her partner are likely to expect, and their comfort with the procedures during labor and delivery. For example, research on the birth settings in hospitals in the United States, Germany, France, and Italy found that each country had a somewhat different focus on the

XiXinXing/Shutterstock.com

Modern birth cultures favor less use of obstetrical medications so that the mother is awake, the father is involved, and medical staff are part of the support team.

woman's ability to have control over the birth process, the types of emotional and technical support provided, the availability of childbirth preparation classes, and the focus given to mother–child and father–child bonding in each setting (Scopesi, Zanobini, & Carossino, 1997). In a comparison of childbirth experiences in seven countries, Canada, the United States, the United Kingdom, Azerbaijan, Lithuania, the Russian Federation, and Moldova, significant differences in medical practice were observed. Practices in the United States and Canada were the most "medicalized." Practices in the former Soviet countries were the least, with the United Kingdom in between. These differences included the frequency of induced labor, the use of fetal heart monitors during labor, the rates of cesarean deliveries, and the presence of a partner during labor and delivery. Over all, only about half the women were very satisfied with their birth experiences (Chalmers 2012).

Studies of immigrants giving birth in a new country examine problems of communication between women, their families, and the childbirth professionals that undercut the woman's sense of confidence and control. Table 4.3 summarizes some

Table 4.3 Mental Health Stressors and Possible Psychological Reactions

Pre-immigration experiences	• Psychological issues related to past experiences of war, displacement, rape, torture, survival in refugee camps, death of close relatives • Post-traumatic stress disorder (fear, nightmares, lack of control over a situation, depression, hopelessness) • Powerlessness over decision to migrate
Adjustment	• Stress related to the loss of job, housing, financial problems, lack of English language skills, lack of knowledge and skills for everyday activities, stress related to lack of knowledge of services
Wellbeing of overseas family	• Feelings of guilt for not contributing enough to family overseas • Family members may be missing or living in difficult or dangerous circumstances
Lack of knowledge of antenatal care system and birthing practices	• Fear of difference in health care and birthing practices in host country • Inability to navigate the health system due to cultural or language barriers
Traditional beliefs	• Fear of illnesses due to not practicing traditional practices • Fear of being cursed by overseas relatives • Fear to displease relatives and/or ancestral spirits • Adjustment stress due to practicing traditional practices
Female genital mutilation	• Stigma, feeling different from others, fear of potential procedures, lack of voice • Confusion. Some women feel proud of being circumcised. When entering western culture, the woman may feel different or incomplete and this may impact on mental health.
Antenatal testing, genetic counselling	• Fear of tests, lack of choice about continuing or terminating a pregnancy due to religious beliefs
Sex preference	• Negative emotions linked to having a female fetus, lack of choice about continuing or terminating a pregnancy due to family pressure
Arranged/early marriage, unwanted/unplanned pregnancy	• Hopelessness, lack of personal voice, lack of choice about continuing or terminating a pregnancy, lack of choice about remaining married, or separation or divorce due to family pressure and religious beliefs
Inflicted violence	• Post-traumatic stress disorder (fear, emotional distress, lack of control, frequent use of psychotropic medication)
Lack of support	• Loneliness, isolation, nostalgic feelings, burden of care for the newborn infant, lack of extended family support in Australia
Lack of knowledge and skills to care for newborn child	• Fear that the infant might die due to inadequate care, anxiety and fear that something is not right with the infant, self-blame for inadequate care, fear of reactions to immunization
Breast feeding problems	• Stress related to insufficient lactation, fear that the infant is hungry, stress related to introducing formula and solid foods

© 2018 Cengage

of the stressors that face immigrant women and their partners in Australia as they go through pregnancy and childbirth in a new, unfamiliar birthing environment. Some of these stressors relate to difficulties such as poor health care or exposure to violence that precede the transition to a new country; others relate to the lack of trust in or understanding of contemporary health care practices. Immigrant women are especially distressed by behaviors that they perceive to be unkind, rushed, or unsupportive during their labor and delivery (Queensland Government, 2012). Efforts should be made to provide information about the key elements of the birth culture for women who are not familiar with it in order to foster trust and improve birth outcomes.

FURTHER REFLECTION *What do you know about cultural rituals, practices, and beliefs about pregnancy in your family, ethnic group, or community? How would you describe these cultural practices along the dimensions of solicitude vs. shame or adequacy vs. vulnerability?*

Applied Topic: Abortion

OBJECTIVE 7 Apply the psychosocial perspective to the topic of abortion, including the legal context, its social and emotional impact on women, and men's views.

What Is Abortion?

Abortion is the termination of a pregnancy before the fetus is able to live outside the uterus. We want to encourage you to analyze the applied topic of abortion from a biopsychosocial perspective. Abortion is a biological process that impacts living beings, including fetus and mother. Information from the chapter about genetic inheritance, fetal development, and the physiological experiences of pregnancy are all related to the biological system. Abortion is a psychological process, involving decision making, fears, hopes and other emotional responses, life plans, and goals. Abortion is also a social, cultural, and societal process, embedded in a complex context of relationships, beliefs, laws, regulations, resources, and community norms.

Each year, thousands of pregnancies are terminated through spontaneous abortion, usually referred to as miscarriage. However, the focus of this section is on the *voluntary* termination of pregnancy. In obstetrical practice, abortions are induced differently depending on the time from the woman's last menstrual period. In the first trimester, medical and surgical abortions can be performed. In the second trimester, several different types of surgical procedures are considered. In the third trimester, abortions are only performed under specific medical circumstances. Guidelines for these abortions differ across the states and depend on the evaluation of fetal viability, maternal health-related risks, and state law (American Pregnancy Association, 2015c; Cunningham et al., 2014).

A nonsurgical approach to abortion, sometimes referred to as medical abortion, was developed in France in 1988 with the drug RU-486, now called mifepristone. The drug was approved by the Food and Drug Administration (FDA) in the United States in 2000 to be prescribed by a physician who can make a referral to a hospital or surgeon should a surgical abortion be required ("Congress and RU-486," 2001). The drug, called Mifeprex, combines two drugs: mifepristone, which blocks the hormone that sustains the uterine lining, and misoprostol, which causes uterine contractions. The combination of these drugs ends the pregnancy. Administration of Mifeprex typically requires several clinic visits. Based on data from 1.5 million women, the drug was found to be 92 percent to 95 percent effective in ending pregnancy within the first 49 to 63 days (Boonstra, 2013).

The Legal and Political Context of Abortion in the United States

At the heart of the abortion controversy in the United States is the conflict between society's responsibility to protect the health and reproductive rights of a woman and its responsibility to protect the rights of an unborn child. On one side are those who argue that a woman's human rights include self-determination and reproductive autonomy, including the right to privacy in consultations with her health care providers, and the right to choose or reject motherhood. In countries where legal abortions are restricted or prohibited, thousands of women resort to illegal procedures, resulting in death or impaired sexual and reproductive health. Since women bear the physical consequences of unintended pregnancies, access to the benefits of medical science to end those pregnancies is a central component of the case for legalized abortions.

On the other side are those who seek to treat fertilized eggs, embryos, and fetuses as separate legal persons deserving of the state's protection since they are incapable of protecting their own interests. This argument includes recognition of the prenatal embryo/fetus as a person who is legally entitled to the same parental support and protection as a child after birth. Those who oppose abortion from a religious perspective view it as a sin, violating a holy commandment against taking a human life. Since the well-being of a woman and her unborn fetus are intimately entwined, some argue that we cannot truly separate the well-being of one from the other (Fried, 2013).

A key developmental concept requiring clarification in the abortion controversy is the age at which the embryo is considered an individual and thus entitled to protection by the state. In 1973, in the case of *Roe* v. *Wade*, the U.S. Supreme Court proposed a developmental model to address that issue. The court supported the division of pregnancy into three trimesters and considered abortion a woman's right in the first trimester, guarded by the U.S. Constitution's protection of privacy. The court said that in the second trimester, some restrictions could be placed on access to abortion because of its risk to the mother; however, the fetus's rights were still not an issue during this period. In the final trimester, when the fetus was regarded as having a good chance of surviving outside the uterus, states could choose not to permit

The abortion controversy continues to highlight the social, political, religious, and cultural significance of the prenatal period. What do you see as the eventual resolution of this controversy in the United States?

abortion. This ruling endorsed a woman's right to full control over the abortion decision until the fetus reached a point of **developmental viability**. At that point, the court ruled, society's responsibility to the unborn child outweighs the woman's right to freedom and privacy.

As we discussed earlier in the chapter, medical practices and new technologies are having an impact on fetal viability. Whereas in the past, 24 weeks of gestational age was considered a lower threshold for viability, interventions at some specialized centers are successful in saving some babies at 22 to 24 weeks, leaving open the question of viability and related policy implications.

In the years since the *Roe v. Wade* decision, the Supreme Court has ruled unconstitutional the state laws that tried to regulate abortions. However, the states have a wide range of regulations, some permitting and others prohibiting restrictions of various types. The main areas where restrictions have been imposed are as follows: restrictions on abortion after a specified point related to **fetal viability**, abortion reporting requirements, clinic access, parental involvement, mandatory delay and state-directed counseling, restrictions on insurance coverage of abortion, state funding of abortion for Medicaid recipients, partial-birth abortion bans, and restrictions on later abortions. For details about the restrictions that apply in each state, visit the website of the Guttmacher Institute, www.guttmacher.org.

In general, the U.S. Supreme Court has ruled that states ought not to impose an undue burden on a woman by placing major obstacles in her way if she seeks an abortion before the fetus has reached viability. However, from 2010 t0 2015, states have enacted a total of 282 provisions restricting some aspect of access to abortion. According to a report issued by the American College of Obstetricians and Gynecologists (ACOG, 2014), many of these restrictions are neither evidence-based nor ethical:

> Abortion, although still legal, is increasingly out of reach because of numerous government-imposed restrictions targeting women and their health care providers. Recent years have seen a dramatic increase in the number and scope of legislative measures restricting abortion, with 22 states enacting 70 measures restricting abortion care in 2013. The greatest number of state-level restrictions ever enacted in 1 year was in 2011, with 92 restrictions. Health care providers face laws inappropriately unique to the provision of abortion that mandate procedures and counseling that are not evidence-based or ethical. The College, along with other medical organizations, opposes such interference with the patient–provider relationship, confirming the importance of this relationship in the provision of high-quality medical care. (ACOG, 2014)

Many states require counseling and informed consent, often with a mandatory waiting period, before the abortion can be performed. Restrictions also focus on the requirement for minors to get parental consent before having an abortion. Most states require reporting from physicians who perform abortions; some states require physicians to have specific hospital admitting privileges in order to perform abortions. At present, women are not required to have the consent of their husbands or the child's father before having an abortion (Nash, Gold, Rathbun, & Vierboom, 2015).

The impact of the anti-abortion movement has been to limit women's access to abortion resources across the country. By attacking and even killing physicians who perform abortions, by intimidating women as they approach clinics, by supporting measures that result in the loss of funding for clinics, and by pressing for legislation that impacts abortion practices, the availability of safe, legal abortion services has declined. One report found only 51 percent of obstetrics and gynecology residency programs routinely offer abortion training. What is more, although family medicine physicians are the most likely to serve women who are in the early stages of pregnancy and may be considering abortions, only 5 percent of family medicine residency programs include abortion training (ACOG, 2014). From 1982 to 2005, the number of abortion providers declined almost 50 percent. Most abortion clinics are located in urban areas. In 2014, 89 percent of U.S. counties lacked a single licensed abortion provider. This has had a differential impact on rural and low-income women (American College of Obstetricians and Gynecologists, 2014; Yanow, 2013).

Statistics About Legal Abortions and the Women Who Have Them

The number of reported legal abortions in the United States increased dramatically after the *Roe v. Wade* decision, from 745,000 in 1973 to 1,554,000 in 1980 (U.S. Census Bureau, 1999). Since then, the trend has been a decline in the number of abortions and in the ratio of abortions to live births. Based on data from 2012, the number of abortions in that year was 699,202, with an abortion ratio of 13.2 abortions per 1,000 women ages 14 to 44 (Pazol, Creanga, & Jamieson, 2015). This decline is attributed to a number of factors, including changes in attitudes toward abortion, decline in access to abortion clinics, more effective contraceptive use, and a resulting decline in the number of unwanted pregnancies especially among adolescents.

Some of the characteristics of U.S. women who had legal abortions in 2012 are summarized in Table 4.4. The data suggest that women who have abortions come from a variety of socioeconomic, developmental, and family contexts. Based on this diversity, one can infer that women have different reasons for having an abortion. The age group from 20 to 24 years old had the highest rate of abortions (32.8 percent of all abortions), followed by those from 25 to 29 (25.4 percent of all abortions) and 30 to 34 (16.4 percent of all abortions). White non-Hispanic women had 37.6 percent of all legal abortions. Most of the abortions were performed at less than 13 weeks gestation. Roughly one in three women had experienced two or more prior abortions.

Table 4.4 Legal Abortions in the United States: Selected Characteristics, 2012

Total legal abortions in 2012:	699,202
Abortion ratio (no. of abortions per 1,000 women ages 14–44):	13.2
Age of women having abortions (%)	
Under 15	0.4
15–19	12.2
20–24	32.8
25–29	25.4
30–34	16.4
35–39	9.1
40 and over	3.7
Marital status of women having abortions (%)

The Psychosocial Impact of Abortion

What do we know about the impact of abortions on women? Are abortions medically risky? The mortality rate for women who experience a legal, induced abortion (0.6 per 100,000 women who have an abortion) is substantially lower than the mortality rate for women who carry a pregnancy to term and deliver a live baby (8.8 per 100,000 live births) (Raymond & Grimes, 2012).

How do women cope emotionally with the experience of abortion? Although the physical risks of abortion are less than those associated with childbirth, this still leaves unanswered questions about the emotional or psychological risks. Despite a substantial body of research, these questions are difficult to answer. Research on the emotional and mental health consequences of abortion continues to face methodological criticisms and inconsistent findings (Cougle, Reardon, & Coleman, 2005; Schmiege & Russo, 2005). Methodological questions include the following:

1. What are some differences between women who have had abortions and are willing to participate in research and those who are not?
2. What are the appropriate comparison groups in studies of abortion? For example, how do reactions to abortion compare with the mental health consequences associated with elective plastic surgery, breast reconstruction, or other surgeries?
3. What are the appropriate outcome measures?
4. When, how often, and for how long should the consequences of abortion be assessed?
5. How should differences in age, family status, and economic status be considered in this research?
6. How should differences in the reasons for having an abortion be considered in this research?

— CASE STUDY Karen and Don —

This case explores the decision about giving birth to an infant with severe genetic anomalies.

A young couple, whom we will call Karen and Don, wanted to start a family but were troubled by a puzzling coincidence. A few years before, Don's sister had given birth to a daughter with abnormalities that matched a pattern in Don's younger brother: a heart defect, a double thumb, a club foot, and severe mental retardation.

Karen and Don went to a human genetics clinic and began a process of discovery. With the help of a counselor, they constructed a family tree … identified potential carriers of the disorder in Don's family, and [the counselor] persuaded them to get a blood test. Don's test confirmed the young couple's worst fear: He was a carrier and potential children were at risk. …

The impact of these discoveries on Don's family was profound. When blood testing revealed that his mother was not a carrier, she was relieved of a burden of guilt she had secretly carried for years… The same information implicated Don's father; his reaction to it can be gauged by his refusal to have a blood test … Don himself fell into guilty silence. Not only was he the carrier of a genetic defect, he was disappointing his wife, who desperately wanted to have a baby. He thought of artificial insemination, rejected the idea, and came close to abandoning altogether the idea of having children. Then, suddenly and surprisingly, after beginning to look into adoption, Karen discovered she was pregnant. …

A process of intervention began for Karen and Don when amniocentesis revealed that theirs was to be a child with severe abnormalities. "Maybe I should go ahead and have the child," she remembered thinking, "because it could be the only one I'll ever have." But they had already decided under what conditions they would terminate their pregnancy.

Karen's abortion was no easy matter for her. "It's not like I just lost the baby, I had a miscarriage. I willfully went in and terminated a pregnancy, and it was hard for people to deal with it. Some people think it was the kind of thing … you go in and you're knocked out and you wake up and you're not pregnant anymore. And that's not the way it was at all. They induced labor, and I was in labor for ten hours, and I delivered a child. I was awake. My mother called to find out how I was doing afterward, but then dropped the subject. When I went back to work, everyone acted like things should be normal, like nothing had ever happened, and I was definitely mourning.

McAdams and E. de St. Aubin (Eds.), *Generativity and Adult Development: Psychosocial Perspectives on Caring for and Contributing to the Next Generation*, Washington, DC: The American Psychological Association.

CASE ANALYSIS Using What You Know

1. Try to put yourself in the roles of the main characters in this case: Karen, Don, Karen's mother, Don's mother, Don's father. How might you react?
2. Analyze how the biological, psychological, and societal systems are involved in understanding the issues faced by Karen and Don.
3. Compare how these experiences might influence the marital relationship for Karen and for Don.
4. Evaluate the ethical considerations in this case.
5. Examine the case through a cultural lens. In what ways do cultural issues related to pregnancy, childbirth, and abortion come into play in this case?

Findings of a task force convened by the American Psychological Association on Mental Health and Abortion reviewed numerous studies. After evaluating their methodological strengths and weaknesses, the task force reached the following conclusions:

1. The majority of women who terminate their pregnancy through a legal, first-trimester abortion do not have any mental health problems.
2. There is no systematic evidence that having an abortion causes mental health problems.
3. The risks of mental health problems associated with the first trimester termination of an unwanted pregnancy are about the same as risks for mental health problems among women who deliver an unwanted child (Major et al., 2009).

In addition, the task force found that "other risk factors, including poverty, prior exposure to violence, a history of emotional problems, a history of drug or alcohol use, and prior unwanted births place women at risk of experiencing both unwanted pregnancies and mental health problems after a pregnancy, irrespective of how the pregnancy is resolved. Failures to control for these co-occurring risk factors may lead to reports of associations between abortion history and mental health problems that are misleading" (TFMHA, 2008).

The typical emotional reactions of women who have had abortions are both positive and negative: relief at having taken control over one's situation by ending an unwanted pregnancy, and regret over the loss (Fergusson, Horwood, & Boden, 2009). In a study of more than 400 women 2 years after they had an abortion, 70 percent felt they had made the right decision. Especially when the pregnancy was unwanted and the abortion was performed within the first 12 weeks, women generally resolve any negative feelings and thoughts they may have had soon after the abortion (Adler et al., 1990). However, roughly 30 percent of women experience some emotional distress as they look back on their decision (Bradshaw & Slade, 2003).

Women differ in the reasons they give for having an abortion. In one study, 80 Norwegian women were interviewed at 10 days, 6 months, and 2 years after their abortion. Some of the reasons they gave as most important for the decision to have an abortion were education, job, finances, being tired and worn out, having enough children, the partner does not want children, and pressure from the male partner to have an abortion. At 6 months and 2 years, the strongest predictor of women's emotional distress associated with the abortion was feeling pressure from their partners to have the abortion. Women who said they had enough children had somewhat better psychological outcomes at 2 years than others (Broen, Moum, Bodtker, & Ekeberg, 2005).

Another factor related to post-abortion adjustment is a woman's views about the acceptability of abortion within the cultural context of her family's and community's beliefs (Wang & Buffalo, 2004). Some women perceive that having an abortion is unacceptable among their family and friends. They may even go so far as to try to keep the abortion a secret because they believe others will despise them for their decision. Not surprisingly, women who believe that abortion is an acceptable solution to an unwanted pregnancy and that abortion is also acceptable to their friends, family, and partner are less likely to experience strong feelings of regret or emotional upset following an abortion. Religious beliefs, childbearing motives, and the woman's awareness of community opinions influence her own attitudes toward abortion.

A review by the Academy of Medical Royal Colleges in London (AMRC, 2011) examined the results of all studies published between 1990 and 2011 on the emotional reactions to abortion. Following consideration of the limitations in these studies, the AMRC offered the following conclusions about the literature:

- Unwanted pregnancy increases a woman's risk of problems with her mental health.
- A woman with an unwanted pregnancy is as likely to have mental health problems from abortion as she is from giving birth.
- A woman with a history of mental health problems before abortion is more likely to have mental health problems after abortion.
- Circumstances, conditions, behaviors, and other factors associated with mental health problems are similar for women following abortion and women following childbirth.
- Pressure from a partner to terminate a pregnancy, negative attitudes about abortion, and negative attitudes about a woman's experience of abortion may increase a woman's risk of mental health problems after abortion.

Based on their assessment of the literature, the AMRC suggested that whereas legal abortion is a relatively mild procedure that does not threaten a woman's health, more attention should be given to the psychological and societal circumstances that are associated with unwanted pregnancies.

Men's Reactions to Abortion

Although abortion is often construed as a women's issue, women and their unborn babies are not the only people affected by the abortion decision. In 1976, the Supreme Court ruled that a woman did not need the consent of her husband or the child's father to have an abortion. Since that decision, the Supreme Court has supported a woman's independence from her husband or a child's father with regard to reproductive decision making. Men do not have a right to be notified about a woman's decision to have an abortion nor do they have a right to prevent an abortion. Even when men object to a woman's decision to carry a baby to term, they may still be required to contribute financially to the support of the child. Informal agreements between partners can allow men to have a greater role in the abortion decision. For example, if a woman wants an abortion, but the child's father is opposed, the couple can create a binding agreement that the man will cover the medical expenses of childbirth and assume legal parenthood (FindLaw, 2016). However, questions about the legal rights of fathers to determine the fate of their unborn children are still being raised, and the laws will probably continue to be challenged as fathers become increasingly committed to participation in parenting or resistant to the financial obligations associated with supporting an unwanted child.

Men clearly play a role in many women's decisions about whether or not to have an abortion. They also have their own reactions to the situation. For both of these reasons, there is a need to pursue systematic research about men's reactions to abortion, including their emotional responses and the consequences of the abortion for their future reproductive behavior.

Research suggests that men have ambivalent reactions to their partner's abortion including relief, grief, and sadness, and a desire to support their partners. Men also express a need for counseling programs for the male partners of women undergoing abortion (Coyle, 2007).

In a qualitative study of men's experiences with unintended pregnancy and abortion, a range of reactions were identified. Men differ in the degree to which they take responsibility for the pregnancy. In some cases, they viewed the unintended pregnancy as entirely the responsibility of their female partner. In other cases, they accepted shared responsibility. Similarly, men differed in the perception of the role they played regarding the pregnancy outcome. Some believed that their female partner made the decision, excluding them entirely; others felt that the decision was reached together; and still others claimed that they convinced their partner to end the pregnancy through abortion (Reich & Brindis, 2006).

Some research has focused especially on adolescent fathers who may experience feelings of anxiety, anger, and moral conflicts about abortion. Young men feel that they need to be strong for their girlfriends, even if they are feeling their own sense of confusion or loss. Just as for women, the response of men is embedded in their value system and in their relationship with the baby's mother. For young fathers, issues of secrecy and consideration for the girlfriend may prevent them from seeking support for their own feelings.

Research on men's influences on women's reproductive health suggests that women are concerned about their partners' attitudes, especially if they think that having a child or not having a child might result in abandonment (Dudgeon & Inhorn, 2004). Abuse by a partner may be one reason women choose to have an abortion. Women who believe that their partner will love them and their unborn child are more likely to give birth. However, most of the research on the role of men in the abortion decision is based on what women say about how they have taken their partner into account in reaching their decision. More research is needed to learn what shapes men's reactions to unintended pregnancy, their attitudes about abortion, how men contribute to the abortion decision, and how abortion experiences may influence a man's future approach to sexual relationships and paternity. This research needs to be approached from a cultural perspective, recognizing the dynamic interplay of gender roles, family structure, and religious and ethnic values.

The debate surrounding the legalization and availability of abortion services is an excellent example of a psychosocial controversy. Embedded in this controversy are key human development issues: When does human life begin? When is a fetus viable—that is, capable of life outside the uterus? What is society's responsibility to unborn children? To women of childbearing age? What is the impact of an abortion on a woman's physical health, psychological well-being, and future childbearing? What is the impact of bearing and rearing an unwanted child on a woman's physical health and psychological well-being? What is the impact of being an unwanted child? What are the rights of fathers with respect to a woman's decision to have an abortion? What are the rights and responsibilities of parents in regard to an adolescent's abortion? The politicization of the abortion controversy often overshadows the personal dilemmas that face women and men as they confront this difficult decision.

FURTHER REFLECTION *Summarize your understanding of the politics of abortion. Why is this a political topic? Why would a person's views on abortion be relevant to how he or she would serve as a member of the state or federal legislature? How does your understanding of the content of this chapter on pregnancy and the prenatal period influence your own thinking about a woman's reproductive decisions?*

CHAPTER SUMMARY

OBJECTIVE 1 Summarize the process through which genetic information is transmitted from one generation to the next.

Genetic inheritance links each new infant to a specific ancestry and to the evolutionary history of the species. The important work of the genes is to produce proteins, which then guide cellular formation and functioning. The laws of heredity explain how genetic information is passed from parents to their offspring. The genotype is the biochemical information encoded in the DNA; the phenotype is the expression of that information, which can be influenced by patterns of interacting genes, or the interaction of genes and the surrounding cellular, social, and physical environment. Epigenetic marks and mutations can alter the expression of genes in the person and in his or her offspring.

OBJECTIVE 2 Differentiate the contributions of genetic factors to individuality through their role in controlling the rate of development, their influences on individual traits, and the genetic sources of abnormalities.

Individual differences are due to a combination of the many variations in environment and experience that confront a growing person and the variability built into the biological mechanisms of heredity. Genetic factors contribute to differences in the rate and timing of development, to patterns of individual characteristics such as temperament or intelligence, and to anomalies that may result in abnormal development. The norm of reaction is a way of conceptualizing the probabilistic outcome of various phenotypes given a particular genotype. Through advances in scientific technologies, we are entering an era when it is possible to intervene to influence the genotype, thereby modifying its contribution to individual differences. These advances are accompanied by significant ethical considerations. The more we study human genetics, the more we learn about the dynamic and ongoing interplay of genetic information and environmental factors.

OBJECTIVE 3 Trace the process of prenatal development from fertilization through three trimesters of pregnancy, including an understanding of infertility, alternative means of reproduction, and related ethical considerations.

The 38 weeks of prenatal development, including the germinal period, the embryonic period, and the fetal period, involve a rapid differentiation of body organs and a gradual integration of survival functions, especially the ability to suck and swallow, the regulation of breathing and body temperature, and the maturation of the digestive system. Sense receptors are prepared to respond to stimulation long before they are put to use. The CNS, which begins to take shape in the third and fourth weeks after conception, continues to develop and change throughout the prenatal period and into childhood and adolescence. The newborn's neurobehavioral capacities are influenced by the quality of the prenatal environment, including potential disruptions to the CNS. During weeks 3 through 9 of the prenatal period, fetal development is especially vulnerable to the disruptive impact of teratogens, a wide range of viruses, medications, and environmental toxins that can harm organ differentiation and the maturation of the CNS. Medical advances are providing a range of increasingly effective alternative approaches for reproduction for couples who are unable to conceive and do not want to adopt a child. Each of these alternatives is accompanied by complex ethical considerations about the nature of parental rights and the fate of artificially produced embryos.

OBJECTIVE 4 Describe the birth process and analyze factors that contribute to infant mortality.

Childbirth is described in five stages: early signs that labor is approaching, the onset of labor, transition from labor to delivery, birthing, and the postpartum period. The length of labor is quite variable, with first births usually taking longer than subsequent births. Infant mortality rates are influenced by the quality of prenatal care, the availability of quality medical facilities for newborns, and risks associated with low birth weight often coupled with preterm births. The United States ranks behind many industrialized countries in the number of infants who die before the age of 1.

OBJECTIVE 5 Analyze ways that the pregnant woman and the developing fetus influence each other, focusing on how pregnancy affects a childbearing woman and expectant father, and the impact of environmental influences on fetal growth, such as a woman's age, drug use, nutrition, environmental toxins, and stress.

During pregnancy, the mother and the fetus are interdependent. The fetus alters the mother's physical state, fetal movements provide an ongoing source of stimulation, and pregnancy can introduce new risks to maternal health. Pregnancy affects a woman's social roles and social status. Pregnancy influences how people, including the baby's father, treat a woman and what resources become available to her. A woman's physical well-being and emotional state along with her attitude toward her pregnancy and her developing attachment to her unborn child set the stage for the quality of her parenting after the child is born.

Characteristics of the mother, her lifestyle, and her physical and cultural environments all influence fetal development. Of special concern are the mother's age, any drugs she takes during her pregnancy, her exposure to certain diseases and environmental toxins, exposure to stress, adequacy a woman's diet, and safety of the food she eats. Whereas each of these factors is known to have an impact on fetal development, increasing attention is being given to their cumulative impact. Infants conceived by women living in poverty are exposed to many of the environmental hazards that are known to result in low birth weight and physical abnormalities. Expectant fathers have different reactions, which influence their own well-being as well as the emotional and physical well-being of their pregnant partners. Men's outlook on their impending fatherhood reflects their own psychosocial maturity, their perceptions about the quality and stability of the relationships they are in, the stability of their employment, and their readiness to embrace the responsibilities of fatherhood.

OBJECTIVE 6 Examine the impact of culture on pregnancy and childbirth.

The experiences of pregnancy and childbirth occur in a cultural context. The birth culture provides a set of guidelines for behavior, attitudes toward and beliefs about restrictions on the woman's activities, the availability of resources, and the treatment of a pregnant woman by others. Cultures vary in their attitudes toward pregnancy along dimensions of solicitude versus shame and adequacy versus vulnerability. Even within cultures, there may be variability in attitudes depending on the age and social status of a woman and the timing of her pregnancy. Health providers are urged to be sensitive to cultural expectations about pregnancy and childbirth when providing care to recent immigrants or to women who are going through childbirth in an unfamiliar cultural context.

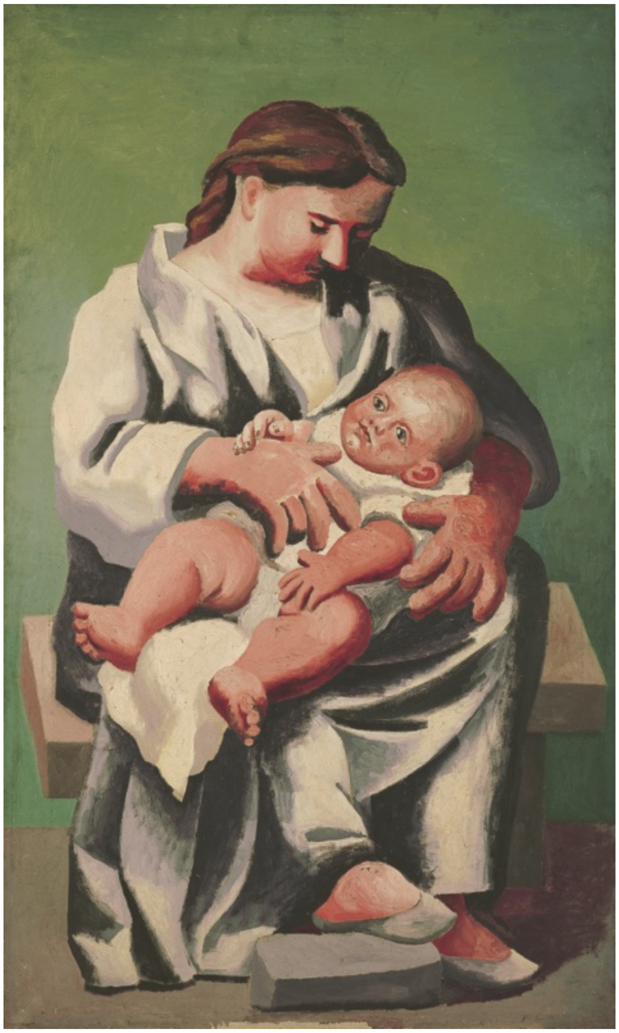
OBJECTIVE 7 Apply the psychosocial perspective to the topic of abortion, including the legal context, its social and emotional impact on women, and men's views.

The applied topic of abortion illustrates the integration of the biological, psychological, and societal systems as they impact an important issue in the field of human development. The decision to abort reflects the mother's attitude toward childbirth; her criteria for a healthy, normal child; her age and economic resources; and her access to a safe means of ending the pregnancy. Decisions about abortion are often tied to a woman's perceptions about her partner and his attitudes toward the unborn child. Decisions about abortion also reflect the culture's attitudes about the moral implications of ending a life after conception and the legal principles about when the fetus itself has a right to society's protection. Finally, the decision to abort is related to the safety, accessibility, and expense of the procedure. The research on abortion-related decision making and the mental health consequences of abortion are replete with difficulties. Men do not have a legal right to impose their views about a partner's abortion-related decision; however, they may work with their partner to create informal agreements about this decision.

The stage is now set to consider the remaining life stages in a psychosocial context. In this chapter, we have discussed the emergence of a child into an existing family, community, and cultural network. Although much attention has been given to the early period of childhood (birth through age 3) for subsequent cognitive, social, and emotional development, the analysis of the prenatal period suggests that the dynamic epigenetic process is already under way before birth. The care provided for expectant parents is intimately connected to the potential for optimal development in their offspring.

CASEBOOK

For additional cases related to this chapter, see the case of "Lonita and Tano," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman, pp. 32–37. This case introduces the challenges of supporting a healthy pregnancy for a new immigrant couple with few financial resources.



culture-images/Lebrecht

In 1921, Picasso's first son Paulo was born. In that year, he painted at least 13 works focusing on mother and child. In this image, a large, monumental style canvas, Picasso brings the classical tradition of Greek and Roman sculpture together with the intimacy of a loving relationship. The mother provides safety, security, and a calming affection. The baby gazes peacefully in her arms. We see the process of mutual adaptation as mother and infant establish patterns of meaningful interaction and build a foundation for trust.

LEARNING OBJECTIVES

1. Describe characteristics of newborns and explain the challenges facing low-birth-weight babies.
2. Identify important milestones in the maturation of the sensory/perceptual and motor systems. Describe the interactions among these systems during the first 2 years of life. Explain how brain development in infancy is tied to the maturation of the sensory and motor systems.
3. Discuss the development of sensorimotor intelligence, including an analysis of how infants process information, organize experiences, conceptualize causality, and understand the properties and functions of objects.
4. Summarize the beginnings of language competence from birth through the first 2 years of life.
5. Analyze social attachment, the process through which infants develop strong emotional bonds with others, and describe the dynamics of attachment formation during infancy.
6. Examine the nature of emotional development, including emotional differentiation, the interpretation of emotions, and emotional regulation. Analyze the concept of temperament as an organized aspect of emotional reactivity.
7. Explain the psychosocial crisis of trust versus mistrust; the central process through which the crisis is resolved, mutuality with the caregiver; the prime adaptive ego quality of hope; and the core pathology of withdrawal.
8. Evaluate the critical role of parents and caregivers during infancy, with special attention to issues of safety and nutrition; optimizing cognitive, social, and emotional development; and the role of parents and caregivers as advocates for their infants.

INFANCY (FIRST 24 MONTHS)

CASE STUDY: A Close Look at a Mother-Infant Interaction

Newborns

Developmental Tasks
- The Development of Sensory/Perceptual and Motor Functions
- Sensorimotor Intelligence: Processing, Organizing, and Using Information
- Communication
- Attachment
- Emotional Development

CASE STUDY: The Cotton Family

The Psychosocial Crisis: Trust Versus Mistrust
- Trust
- Mistrust

The Central Process for Resolving the Crisis: Mutuality with the Caregiver
- Coordination, Mismatch, and Repair of Interactions
- Establishing a Functional Rhythm in the Family
- Parents with Psychological Problems

The Prime Adaptive Ego Quality and the Core Pathology
- Hope
- Withdrawal

Applied Topic: The Role of Parents
- Safety and Nutrition
- Fostering Socioemotional and Cognitive Development
- Fathers' and Mothers' Parental Behaviors
- Parents as Advocates
- The Importance of Social Support

Chapter Summary

— CASE STUDY A Close Look at a Mother–Infant Interaction —

Systems theory invites us to look at infants as dynamic systems, striving to make meaning in the context of numerous daily caregiver–infant interactions. Infants gather information through their sensory and motor actions, monitor the reactions of others, and use that information to form increasingly coherent and complex ideas about themselves and others. In the following interchange between a mother and her 6-month -old infant, we get a glimpse into the kinds of situations that lead to an infant's formation of expectations about the world and his or her place in it.

The mother bends down to nuzzle the infant with her hair. The baby tightly grabs her hair and won't let go when she tries to disengage herself. The mother vocalizes in genuine pain ("Ow") and pulls back with an angry, bared-tooth facial expression. Although the mother's vocal and facial display of anger lasts less than half a second, the infant immediately responds in a defensive fashion. He brings his hands up in front of his face and turns away…The mother's angry display is not just an interesting or novel display or one with no significance; rather it has meaning for the infant. The infant appears to be apprehending danger. The mother immediately perceives the meaning of her infant's change in behavior and quickly changes what she is doing. She uses soothing, cajoling actions and vocalizations to try to repair the interactive rupture. At first, the infant stays behind his hands; then he tentatively peeks out at her. Gradually, over the next 30 to 40 seconds, he begins to smile, and then he smiles and looks at her, until they return to a state of mutual positive engagement.

Source: From "Infants' Meaning-Making and the Development of Mental Health Problems," by E. Tronick, and M. Beeghly, 2011, *American Psychologist, 66*, pp. 109–110.

CASE ANALYSIS Using What You Know

1. Explain the idea of the infant as an open system. What are the resources that the infant needs from the environment? What strategies does an infant have to obtain these resources?
2. Explain the role of facial expressions in this case. What roles do facial expressions play as infants and caregivers strive to understand each other?
3. Describe the sequence of meaning-making that takes place in this case. How might the meaning of this interaction alter future interactions?
4. Can you attribute motivation to the infant's action of pulling his mother's hair? What might it be? How might the mother's understanding of her infant's behavior alter the way she reacts to it?

Infancy is a period of strikingly rapid development. During the first year of life, the infant's birth weight almost triples. (Imagine if your weight tripled within 1 year at any other time in your life!) The baby seems to grow before your very eyes. Parents will remark that they go to work in the morning and their baby seems to have changed by the time they return in the evening. Along with this extraordinary rate of physical growth comes a remarkable increase in control and purposefulness. By the age of 2, the fundamentals of movement, language, and concept formation can be observed.

Infants are marvelously flexible. They do not know the culture or family into which they will be born. They have to be ready to adapt to the practices and customs of their early family or caregiving environment. Thus, we begin to appreciate the central role of culture as it shapes neural pathways and behavioral patterns from the very first days of life.

At the turn of the 20th century, many infants died before their first birthday. As a result, many parents did not invest emotionally in their infants. For example, they often did not name an infant until they were sure that the infant would live. Today, with vast improvements in infant survival each child is taken much more seriously. Safety concerns have prompted laws about car seats for infants, guidelines for putting babies to sleep on their back or side, and the widespread use of monitors in the baby's room to catch signals of infant distress. The medical community is devising complex technologies for saving the lives of babies who are born weighing 1,000 grams (32 oz.) or less. The psychological community is giving attention to infant temperament and the origins of personality, the emergence of language and problem solving abilities, and the potential impact of early stress on development. Research focuses on individual differences among infants even in the very first weeks of life. The Internet is filled with websites and blogs for expectant and new parents. A growing baby industry offers special equipment, foods, toys, books, and other paraphernalia. Sometimes in their exuberance to make a profit from a receptive target market, companies produce infant equipment, toys, and medications that are flawed and dangerous and have to be recalled.

Understanding development during infancy requires that one keep in mind that a genetically guided pattern of growth and development is in continuous interaction with complex and changing social and physical environments. The infant's capacities change, bringing the baby into interaction with new facets of the environment. The burgeoning field of cognitive neuroscience provides insights into the intimate interactions of sensory, motor, and social experiences and neural development. The repetition of daily experiences shape the infant's neural pathways, sculpting patterns of thought and behavior.

Five major developmental tasks are especially critical during infancy:

- Establishment and coordination of the sensory, perceptual, and motor systems
- Elaboration of information-processing capacities and sensorimotor intelligence
- Emergence of early communication skills
- Formation of attachments
- Differentiation of the emotional system

This chapter begins with a description of the physical status of the newborn and then discusses each of the five developmental tasks. The psychosocial crisis of infancy—trust versus mistrust—is explored as a way of thinking about the foundational orientation toward self and society. The applied topic at the end of the chapter analyzes how parents and caregivers can play key roles in promoting optimal development in infancy while laying the foundation for future growth. ●

Newborns

OBJECTIVE 1 Describe characteristics of newborns and explain the challenges facing low-birth-weight babies.

In the United States, the average full-term baby weighs 3,300 grams (7 to 7.5 pounds) and is 51 centimeters (20 inches) long. Boys are slightly heavier and longer than girls. At birth, girls' nervous systems and bones are about 2 weeks more mature than boys'.

In the first minute after birth, and then again at 5 minutes, the newborn's life signs are evaluated using the **Apgar scoring method**, named for its originator Virginia Apgar (see Table 5.1). Five life signs are scored on a scale from 0 to 2: heart rate, respiratory effort, muscle tone, reflex irritability, and body color. A score of 7 to 10 means the infant is in good condition. Scores of 4 to 6 mean the infant is in fair condition and may require the administration of supplemental oxygen. Scores of 0 to 3 suggest an extremely poor condition and the need for resuscitation. Even among the infants who score 7 to 10, those with scores of 7 or 8 show less efficient attention and poorer cognitive processing than the higher scoring infants. The most important use of the Apgar scoring method is for evaluating the need for immediate intervention; not as a means of assessing subsequent development. The Apgar score does not explain the source of the difficulty; it provides an indication about whether some level of intervention is needed (U.S. National Library of Medicine, 2014).

Babies differ in their physical maturity and appearance at birth. Differences in physical maturity have important consequences for the capacity to regulate survival functions such as breathing, digesting, waking, and sleeping. Infants who weigh less than 2,500 grams (about 5 pounds, 8 ounces) are called **low-birth-weight babies**. Low birth weight may result from prematurity (i.e., being born before the full period of gestation). It may also result from the mother's inadequate diet, smoking, or use of drugs, as discussed in chapter 4. These factors tend to lower the fetus's weight for a given gestational age. Babies who are **small for their gestational age** (SGA) are at greater risk for health problems than those who are born prematurely but are of average weight for their gestational age.

Preterm births—that is, births before 38 weeks of gestational age—now comprise about 10 percent of all live births. Although many interventions have been devised to increase the survival of preterm infants, preterm birth is the most common cause of infant mortality. It is associated with a range of medical complications that result in the risk of serious disabilities including cerebral palsy, vision and hearing impairments, and neurological impairments. The earlier the baby is born, the greater the risks of these complications (Center for Disease Control and Prevention, 2015).

The care for preterm infants typically takes place in a neonatal intensive care unit (NICU) of a hospital. Monitoring and management of their breathing, temperature regulation, and heart rate and creation of appropriate stimulation and nurturing in the hospital all contribute to improved chances for survival. Skin-to-skin contact between mothers or fathers and their infants, sometimes referred to as *Kangaroo Care*, has been shown to have benefits for the newborn as well as for parents. It provides a variety of sensory stimulation to the infant and increases the caregivers' confidence and comfort in caring for their baby. Preterm babies who receive *Kangaroo Care* as well as other forms of gentle touching and massage gain weight faster, have improved temperature regulation, and improved alertness as compared to babies who do not receive the systematic comfort of human touch (Feldman, 2011; Feldman & Eidelman, 2004; C. S. Mott Children's Hospital-University of Michigan Health System, 2015).

During the third prenatal trimester, especially between 30 and 34 weeks of gestation, certain self-regulatory functions related to self-calming in the face of unpleasant stimuli and organization of wake-sleep cycles become integrated and synchronized. Babies born before 30 weeks do not have the benefit of positive features of the uterine environment that support these aspects of **self-regulation**. **The Applying Theory and Research to Life** box about very small babies discusses some of the risks for developmental disabilities among babies weighing less than 1,500 grams. Renewed efforts are needed to determine the causes of low birth weight and to prevent as many preterm births as possible.

FURTHER REFLECTION: *Summarize the developmental advantages for full-term babies and the risks for babies who are small for their gestational age. Thinking back to chapter 4, what steps might be taken to reduce the incidence of preterm and SGA babies in the United States?*

Table 5.1 The Apgar Scoring Method

	Score		
Sign	**0**	**1**	**2**
Heart rate	Absent	Slow (less than 100 beats/minute)	More than 100 beats/minute
Respiratory effort	Absent	Slow or irregular breathing	Good crying, strong breathing
Muscle tone	Flaccid or limp	Weak; some flexion of extremities	Active motion, strong flexion of extremities
Reflex irritability	No response	Weak cry, grimace, cough, or sneeze	Vigorous cry, grimace, cough, or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

APPLYING THEORY AND RESEARCH TO LIFE

Very Small Babies

Many babies are born before they reach full gestational maturity. Modern technology has pushed back the boundary of fetal viability to about 24 weeks of gestational age, or a weight of about 500 grams (slightly more than 1 pound). These tiny babies, not much bigger than the palm of your hand, receive weeks of round-the-clock care in their struggle to survive. Hours of intensive care combined with new medical technologies increase the life chances for very tiny babies, yet many of them are at high risk for developmental disabilities associated with their extremely low birth weight and related physical immaturity. In one study of over 4,000 babies born between 22 and 25 weeks of gestational age, 49 percent died and 30 percent lived with disabilities; only 21 percent lived without disabilities (Lee et al., 2010).

Infants who are born at very low birth weights (less than 1500 grams) combined with a low gestational age (under 32 weeks) are much more likely to face chronic health risks including cerebral palsy, asthma, impaired vision, developmental delays, and cognitive impairment compared to babies born at normal weight and full term. Thus extreme prematurity is associated with increased risk of a range of neurological difficulties and disabilities requiring increased levels of medical, educational, and parental care (Hack et al., 2005). However, with improved medical interventions, many of these associated difficulties can be prevented. In a Finnish study, 155 very-low-birth-weight (VLBW) babies were compared to 129 full-term babies. Roughly two thirds of the VLBW babies did *not* have medical complications associated with prematurity (Huhtala et al., 2016).

Very-low-birth-weight babies are clearly different from full-term babies. They are less physically attractive; have higher pitched, unpleasant cries; are more easily overstimulated and more difficult to soothe; and are less able to establish rhythmic patterns of social interaction. In a longitudinal study, Ruth Feldman (2007) compared three groups: high-risk, very small babies born at less than 1,000 grams; low-risk preterm infants (1,700– 1,850 grams); and full-term infants. She was interested in how the coordination of two important biological rhythms, the sleep-wake cycle and vagal tone, differed for the very small babies, and how these biological rhythms might relate to the infant's ability to orient to and react to stimuli.

Vagal tone is a process through which changes in heart rate vary during changes in environmental conditions. Typically, when you breathe in, heart rate increases; when you breathe out, heart rate decreases. Under conditions when a task requires attention and concentration, heart rate increases, which allows for the adaptive mobilization of resources. When the situation becomes more intense or threatening, heart rate slows, leading to conservation of resources and the ability to achieve a more calm state. The vagal system contributes to regulation of arousal and reactivity and is considered to be a basic neural component of self-regulation, information processing, and emotion (Bornstein & Suess, 2000). Feldman hoped to learn whether these biological rhythms would predict infants' ability to modify their reactions to stimuli and to engage in coordinated interactions with their mothers at 3 months.

The first comparison of the three groups was based on data collected at 37 weeks gestational age for the preterm babies and at the second day after birth for the full-term babies. The full-term babies had the most mature sleep-wake cycle and the most mature vagal tone. The low-risk preterm babies scored next, and the high-risk preterm babies had the poorest scores. Both the sleep-wake cycle and vagal tone were related to neurobehavioral orientation.

At 3 months, the infants who showed the poorest vagal tone were more likely to show distress and crying in response to a sequence of stimuli and were less likely to engage in synchronous interactions with their mothers. The study supports the important role of full gestation in allowing for the organization of critical neurobiological rhythms and their subsequent role in fostering emotional regulation, attention, and social interactions. It also helps to account for some of the difficulties parents experience in social interactions with their very small babies.

Several factors help account for the risks that VLBW infants face in subsequent cognitive development. Infants who are born weighing less than 1,500 grams are likely to suffer brain hemorrhages. Moreover, their undeveloped lungs cannot deliver an adequate supply of oxygen to the brain. Chronic lung disease, frequently associated with prematurity, results in breathing problems, feeding difficulties, lung infections, and disrupted flow of oxygen. These insults to the nervous system have an impact on a variety of information-processing skills that can be measured in newborns, including regulation of arousal and attention, visual recognition of familiar stimuli, and reactivity to novel stimuli (Huhtala et al., 2016; Grunewaldt et al., 2014).

ullstein bild/Getty Images

Improvements in neonatal intensive care units (NICUs) include providing a more stimulating, infant-adapted environment while still monitoring basic functions and intervening to enhance chances of survival.

In the Finnish study noted previously, if the VLBW premature babies had none of the medical conditions typically associated with prematurity, their health and quality of life at age 7 was comparable to that of children born full term. However, if the babies had one or more health complications associated with being VLBW, they had notably lower scores on nine dimensions of health and quality of life at age 7 including vision, hearing, breathing, eating, speech, excretion, learning and memory, appearance, and concentration.

Other studies of VLBW babies have begun to focus on the specific aspects of brain architecture that may be compromised as a result of prematurity. Rapid maturation in the CNS takes place during the last prenatal weeks and the first 2 years after birth. When babies born extremely prematurely were compared to full term infants at age 10, many showed evidence of deficits in brain volume and cortical surface area that negatively impacted working memory, motor skills, attention, and self-regulation (Gruenwaldt et al., 2014).

Given the significant challenges faced by very-low-birth-weight babies and their families, research has also focused on evaluating evidence-based programs that provide support and early intervention. First and foremost, chances for survival are improved when very premature babies are delivered in a Level III neonatal intensive care hospital unit. All states have early intervention programs, authorized through the Individuals with Disabilities Education Act, that provide coordinated care for families with infants who are at risk for developmental delays or physical disabilities (National Dissemination Center for Children with Disabilities, 2013).

Critical Thinking Questions

1. List the reasons that very small babies are at risk for impairments of cognitive and sensorimotor functioning.
2. Drawing on information provided in chapter 4, describe neurological development in the last trimester that may be disrupted by preterm birth.
3. Hypothesize why the consequences of neurological damage due to prematurity might become more evident as children get older.
4. What advice would you give to parents of premature infants about how to evaluate their child's developmental level and how to foster a developmentally appropriate set of childrearing expectations?

Developmental Tasks

The Development of Sensory/Perceptual and Motor Functions

OBJECTIVE 2 Identify important milestones in the maturation of the sensory/perceptual and motor systems. Describe the interactions among these systems during the first 2 years of life. Explain how brain development in infancy is tied to the maturation of the sensory and motor systems.

In chapter 4, you learned about the emerging sensory, perceptual, and motor capacities that have been observed during the prenatal period. Depending on his/her gestational age, a newborn has already experienced some vital sensory/perceptual and motor stimulation in utero. However, once the infant encounters the diversity of stimuli in the external environment, the sensory/perceptual system—vision, hearing, taste, smell, touch, motion sensitivity, and responsiveness to internal cues (*proprioception*)—develops rapidly; much more quickly than the motor system. Because most muscle movements are not under the infant's voluntary control in the early months of life, researchers have had to apply considerable ingenuity to study infants' sensory/perceptual competencies. How can you know if an infant detects the difference between the color red and the color orange, or between the mother's voice and the voice of a stranger? We cannot simply ask an infant to point to a circle or press a button to respond to a certain change in color or image. Behaviors such as gazing time, changes in heart rate, strength or frequency of sucking, facial action, head turning, observations of neural firing, and habituation are used as indicators of infants' interest or change in response to stimuli.

Habituation means that the infant's response decreases after each presentation of an identical stimulus. Habituation is one of the most primitive forms of learning and is observed in many mammalian species. Habituation allows the infant to shift attention to new aspects of the environment as certain elements become familiar. When a new stimulus is presented, such as a new level of loudness, or the same tone presented to a different ear, the infant shows an increase in alert responsiveness.

Habituation is one way to determine whether an infant can discriminate between two different stimuli. The researcher first habituates the infant to one stimulus; then a second stimulus is presented. Signs of renewed interest or alertness, measured by changes in heart rate, gazing time, or eye movements, are taken as evidence that the infant has detected a difference between the two stimuli. If the infant shows no new signs of interest or responsiveness, this is taken as evidence that the differences between the two stimuli were too slight to be perceived. Research supports the notion that young infants are capable of forming and retaining a memory for sensory experiences against which they can compare new events.

Brain Development in Infancy

Most infants are born with intact sensory organs and a well-formed brain. The infant's brain contains about 100 billion **neurons**, or nerve cells, which are already connected in pathways that are designed to execute functions related to sensation, perception, and motor behavior as well as to regulate internal systems such as respiration, circulation, digestion, and temperature control (FIGURE 5.1 ▶). The basic architecture of the brain, including regions of the brain and their interconnections, serves as the foundation for all subsequent learning, behavior, and health. The fundamental organization of the brain does not

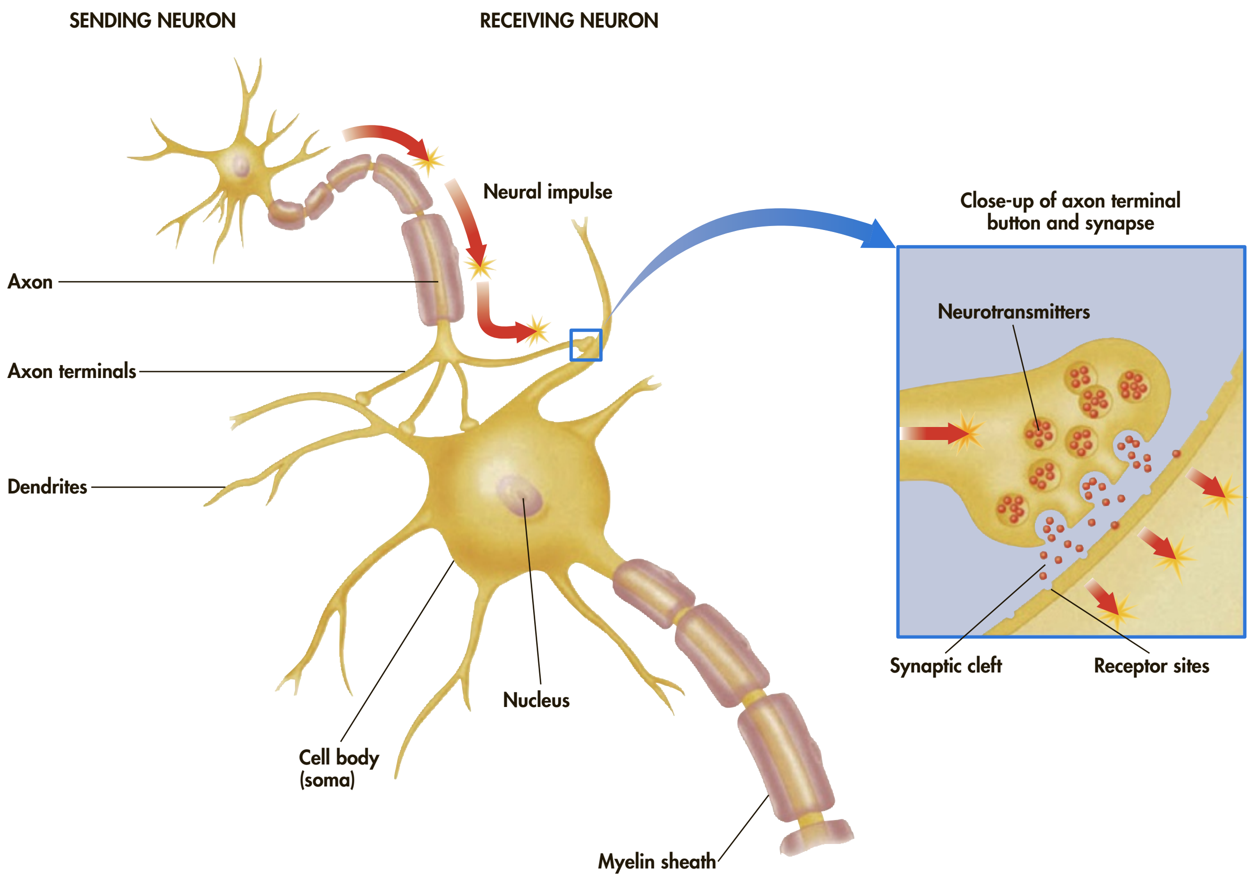

FIGURE 5.1 ▶ MODEL OF NEURON

change after birth, but details of its structure demonstrate **plasticity** (Center of the Developing Child at Harvard University, 2016).

What is **neural plasticity**? It can be thought of in two different but related ways. First, there are all the changes in the interconnections among neurons that occur as a result of learning and experience:

- The formation of neurons.
- The continuing growth of axons and dendrites.
- The formation of synapses, the connections between the axons of one cell and the dendrites of another.
- The sculpting or **pruning** of synapses.
- The production of neurotransmitters, the chemicals that stimulate or inhibit the firing of specific neurons.
- Myelination, the white fatty substance that insulates the neurons and increases the speed of firing from one neuron to the next.
- The production of glial cells that provide stability for the neural network.

The human brain is genetically designed to take in information and use it to guide further thought and action through the establishment of neural pathways. This allows humans to form neural connections that take into account the unique features of their environments and cultures. In the prenatal period, brain cells are formed and the initial organization of the brain structures takes place. Neurons are produced at an astounding rate, and axons and dendrites are formed as the nerve cells begin to link up with each other.

Transient exuberance is the term given to this rapid increase in the number of neurons, dendrites, and synapses that form during the first 2 years of life. As the term suggests, the growth is exceptional, producing far more neurons than will actually be used, and the rate of growth is temporary, preparing the brain to be shaped and organized through experience. Throughout infancy the interconnections among neurons and the speed of firing increase. Changes in the central nervous system improve the infant's ability to organize and use information and to regulate behavior. The early years are the most active period for establishing neural connections, but new connections can form throughout life and unused connections continue to be pruned. Connections that form early provide either a strong or weak foundation for the connections that form later. However, the connections among neurons are not fixed; they can be modified and strengthened through repeated experiences and deliberate practice. These connections are a biological underpinning of all new learning.

Second, neural plasticity can refer to the variety of ways that the brain compensates for injury by making use of alternative resources. For example, severe damage to the left cerebral cortex, where many language-related functions have been located, does not result in lasting language deficits if it occurs prenatally or in the very early postnatal period. As long as the damage does not impact both hemispheres, the infant's language capacities can mature without significant or noticeable disruption or delay (Bates & Roe, 2001).

During the first 3 years, the brain triples in weight and creates about 1,000 trillion connections among the neurons. Different areas of the brain experience an overproduction of synapses at different times, with the visual cortex taking the lead, followed by areas related to hearing and language and the prefrontal cortex where higher level thought and problem solving take place. Then, the pathways are gradually paired down. As a result of early experiences, sights, smells, sounds, tastes, touches, and postures activate and strengthen specific neural pathways, whereas other pathways are not used and decay. The frequency and speed with which nerves fire across a synapse strengthen the stability of the synapse. In the visual and auditory regions, this pruning seems to be completed during the preschool and early childhood periods. In the prefrontal cortex, however, sculpting continues to about age 24, suggesting a much longer window for the organization of higher order reasoning capacities (Giedd et al., 2012).

The process of pruning or sculpting leads to a reduction in plasticity. Although we do not know the exact timing for each area of sensory or motor competence, it is believed that there is much greater plasticity during the period of overproduction of synapses and reduced plasticity once the number of synapses reaches its adult level. For example, in the development of language, all infants are capable of recognizing and uttering sounds from a wide universe of languages. However, after repeated interactions with family members and caregivers, the infant develops strong neural connections for the sounds of the language(s) spoken in the home environment. The neural connections associated with sounds from other languages decay with disuse (Friederici, 2008). Significant injuries or deficiencies in experiences required for optimal functioning become harder to correct as the system becomes more finely organized.

In addition to the production and loss of synaptic connections among neurons, brain development advances through the production of **neurotransmitters**, the chemicals that influence how the nerves grow, how they respond to stimulation, and whether they result in the firing or the inhibition of firing of the neurons. These chemicals influence the growth in dendrites and synapses in various parts of the brain, they alter synaptic strength, and they change in strength following trauma to aid in repair. Experiences such as skin-to-skin contact, which was described as an intervention for preterm infants, contribute to the release of certain chemicals, including oxytocin, that help relieve pain, reduce stress, and provide a sense of security (Carter, 2014). There is a growing interest in how specific aspects of early nurturing might influence the neurochemical environment and thereby alter brain development. The box on **Applying Theory and Research to Life** addresses the role of early stress on brain development.

APPLYING THEORY AND RESEARCH TO LIFE

The Impact of Early Life Stress on Subsequent Brain Development

An infant's brain is especially vulnerable to exposure to stress. Responding to stressors is an important aspect of normal adaptation and development. You can image many possible sources of stress in an infant's daily life such as being hungry, being wet or cold, feeling overstimulated, or wanting physical or social contact. In the face of stress, the body prepares us to respond by increasing the heart rate, blood pressure, and stress hormones, such as cortisol. When an infant's stress response systems are activated within an environment of supportive relationships, these physiological effects are buffered and brought back down to baseline. The result is the development of healthy stress response systems (Center on the Developing Child, 2007). You may recall from chapter 2 that one contribution of object relations theory is the idea that the caregiver creates an interpersonal environment that helps an infant interpret and respond to stress. Thus, in a caring, responsive environment, exposure to stressors can create neural networks that link the stress responses to systems that help to soothe and calm the aroused emotional and physical states.

However, when the stressors are intense and prolonged, without the support of a caring, responsive social environment, the stress response may be prolonged. The accompanying respiratory, circulatory, and hormonal reactions do not return readily to a calm state. Prolonged activation of the stress response system can disrupt the development of brain architecture, increasing the risk for stress-related disease and cognitive impairment.

A violent, neglectful, or erratic caregiving environment may be one of the most central sources of this type of toxic stress. For example, researchers studied the brain functioning of 6- to 12-month-old infants who had been exposed to various levels of inter-parental conflict. Higher levels of inter-parental conflict were associated with changes in the infant's brain architecture associated with more negative emotionality (Graham et al., 2015). Another study explored the relationship of infant attachment status and brain development in early adulthood. Secure attachment is known to emerge in the context of responsive and synchronous caregiving. Those adults who had been characterized as having an insecure attachment in infancy were found to have an enlarged amygdala in early adulthood (Moutsiana et al., 2015). These and other studies provide further evidence of a link between exposure to a stressful parenting environment and brain architecture.

Critical Thinking Questions

1. What are some specific ways that supportive parenting helps infants manage stress?
2. Why might exposure to inter-parental conflict be a source of stress for infants?
3. What might be some links between excessive hormonal activation in infancy, brain architecture, and later cognitive functioning?
4. What is an example of a policy or program that might improve the positive interpersonal environment of infants and young children? How does it work?

As we continue to understand the relationship of brain development to changes in motor behavior, cognition, emotional expression and inhibition, language and communication, interpersonal or social behavior, and self-awareness, keep these two important principles in mind: First, through interactions with the immediate stimulus environment each infant shapes the organization of neural connections, creating very early patterns of familiarity and meaning. Thus, infants contribute to their own brain development by repeating certain actions, attending to certain stimuli more than others, and producing responses in caregivers (Center on the Developing Child, 2016).

Second, throughout childhood, adolescence, and adulthood, more complex cognitive functions, including organized and abstract thought; self-control; appreciation for subtle forms of communication such as sarcasm; capacities for poetry, music, and symbolic art; spatial reasoning; and cognitive flexibility, will emerge. Even though a lot of attention has been given to the importance of brain development in the first 3 years of life, advanced reasoning and expert knowledge require continued maturation of specific areas of the cortex as well as the synchronization of systems in the periods of adolescence and adulthood (Lebel & Beaulieu, 2011; Rubia et al., 2006).

Sensory/Perceptual Development

FIGURE 5.2 ▶ provides a map of the sensory and motor areas of the brain that are related to the infant's emerging capacities. The map suggests that specific functions are guided by activity in certain areas of the brain. However, that is an oversimplification. Early experiences create neural networks that link areas of the brain. For example, movement, body sensations, perception, hearing, and vision are all stimulated as an infant nurses or sucks from a bottle. The more frequently an experience occurs, the stronger and more rapidly the neural connections are made, linking these regions of the brain. Over time, as networks become strengthened through memory and associated emotions, they form foundational neural systems upon which other associations and links can be built. More complex processes such as decision making, learning and memory, emotional expression and recognition, planning, and participation in meaningful social interactions require the interaction and feedback among several areas, including increasing engagement of the prefrontal cortex, a process that unfolds over time with experience and practice (Buschman & Miller, 2007).

It would be difficult to review the full range and detail of sensory capacities that emerge and develop during infancy. Maturation in these domains is breathtaking. Our discussion focuses on those abilities that permit infants to participate in and adapt to their social environment. From birth, sensory/perceptual capacities are vital resources that help infants establish interpersonal ties with their caregivers, gather information about their environment, and cope with sources of stress. Although we provide information on each of the sensory modalities, keep in mind that they typically function together as a multimodal system. Infants not only hear their caregivers, but they also see, smell, and touch them. Voices are normally associated with faces; tastes are linked to smells and textures. Sensory meaning-making takes place with the benefit of information from multiple sources.

Hearing. You may be surprised to learn that hearing rather than vision is the sense that provides the very earliest link between newborns and their mothers. Research has confirmed that the fetus is sensitive to auditory stimulation in utero (Porcaro, 2006). Before birth, the fetus hears the mother's heartbeat. This sound continues to be soothing to the infant in the days and weeks after birth. Newborns show a preference for the sound of their mother's voice over an unfamiliar voice. The speed with which they recognize their mother's voice suggests both increased attention and clear memory for this type of auditory stimulus (Kisilevsky et al., 2009; Purhonen et al., 2005). Infants show a preference for the sound of melodies that their mother sang during the pregnancy and even for the sound of prose passages she read during the prenatal period. An infant's indication of preference for these auditory stimuli is most likely based on familiarity with the sounds from exposure in utero (DeCasper & Fifer, 1980; DeCasper, Granier-Deferre, Fifer, & Moon, 2011; DeCasper & Spence, 1986).

Even in the first weeks of life, a newborn is taking in sensory information about her mother's face, the sound of her voice, her scent, and the way it feels to be cuddled in her arms.

Young infants can distinguish changes in the loudness, pitch, duration, and location of sounds. They can use auditory information to differentiate objects from one another and to track the location of objects (Bahrick, Lickliter, & Flom, 2006; Wilcox, Woods, Tuggy, & Napoli, 2006). Many of these capacities are present among newborns but become increasingly sensitive by 6 months. In one study, infants ages 4 to 6 months were exposed to a looming sound that appeared to come closer or recede from them at a slow or rapid pace. When the sound loomed toward them quickly, the babies leaned back in a defensive strategy to escape the anticipated threat. This suggests that infants have the ability to use auditory information to detect relative speed and distance (Freiberg, Tually, & Crassini, 2001).

The human voice is one of the earliest stimuli to evoke an infant's smile. Infants appear to be particularly sensitive to language sounds (Benasich & Leevers, 2003). In a comparison of newborns and babies 3 months old, the newborns were equally interested in human and monkey vocalizations, and preferred these sounds to synthetic sounds. By 3 months, however, babies showed a clear preference for human over monkey vocalizations, suggesting that human auditory preferences take shape rapidly in the first months of life (Vouloumanos, Hauser, Werker, & Martin, 2010).

Very young babies are able to differentiate basic sound distinctions used in human speech throughout the world. Infants from all language environments are able to perceive and distinguish among the speech sounds that could be used in one or more of the world's languages. By 6 months of age, however, infants prefer to listen to sequences of words spoken in the mother's language rather than in a foreign language, especially if the two languages differ in their overall tone, pauses, and rhythm (Fava, Hull, & Bortfeld, 2014).

During the second 6 months of life, speech perception becomes more tied to the native language. After exposure to a native language, the infant's ability to perceive and produce some sound distinctions declines. Infants begin to produce babbling sounds and attach meaning to certain sound combinations they hear around them, indicating a reorganization of sensory capabilities as the child learns to listen to people speaking a particular language (Altvater-Mackensen, Mani, & Grossman, 2016; Bornstein, 2012; Werker, Yeung, & Yoshida, 2012). This is an example of the plasticity referred to earlier—a fine-tuning of the neural network as a result of experience.

Vision. For sighted, normally developing infants, gazing provides an early and continuing source of information that guides social interactions and learning about the physical environment (Hoehl et al., 2009). Newborns and their caregivers gaze into each other's eyes. Mutual gazing has been shown to have a calming effect on distressed babies. Babies also actively avert their gaze when they need to reduce or withdraw from stimulation. By 4 months of age, babies can follow the gaze of another person toward an object and by 9 months, they use the gaze and head-turning cues of others to direct their attention. By gazing at others and following the gaze of others, babies use vision to form social connections, focus attention, and gain information from others about important objects and activities in their environment (Akhtar & Gernsbacher, 2008; Moore, 2008).

The vast majority of research on sensory development in infancy has concentrated on assessing the acuity or sensitivity of vision. Infants respond to a variety of visual dimensions, including movement, color, brightness, complexity, light-dark contrast, contours, depth, and distance. **Visual acuity** improves rapidly during the first 4 months. Infants are born with a variety of skills for detecting visual stimuli, which matures rapidly into the coordination of visual perception. Pattern and movement perception mature as well. By 2 months, infants form an expectation of a visual sequence. As they watch a pattern of events, they show evidence of anticipating the next event in the sequence (MacMurray & Aslin, 2004). Four-month-old babies perceive objects as adults would. They recognize shapes and colors, and detect complex patterns of motion such as human walking. However, the process of visual cognition—that is, understanding the nature of objects and their physical properties—requires further experience and experimentation.

Visual behaviors also offer a way to assess the infant's cognitive capacities. For instance, the time an infant takes to scan an object and the length of time spent fixating on a novel object are indications of infant intelligence. Shorter fixation time indicates greater speed and efficiency in neural processing (Iliescu & Dannemiller, 2008).

Faceness. Faces are especially salient visual stimuli. Research shows that there is a region of the brain that is active in processing faces; specific nerves fire exclusively in response to faces and not to other visual stimuli. Moreover, among those neurons, some are triggered by particular features of faces such as the round shape, the arrangement and distance between the eyes, or the size of the iris (Nakato et al., 2011; Tsao, 2006). It is as if the brain is organized to build an increasingly complex perception of faces by integrating the recognition of a variety of specific features.

Infants show preference for face-like stimuli (Nelson, 2001). In the early weeks following birth, infants have optimal focus on objects that are about 20 cm away— approximately the distance between the mother's face and her baby cradled in her arms. Newborns can shift focus to scan and keep track of a moving target, but not as easily and smoothly as older babies. Young infants focus their attention on the contours or external borders of objects rather than on the internal details. Thus, if you were holding a young baby, the child might appear to be staring at your hairline or your chin rather than at your mouth.

Faces have many of the properties that infants prefer. The hairline is a type of contour, the eyes provide a light-dark contrast, and the facial expressions provide a changing, moving stimulus. Some 2-day-old infants discriminate between their mother's face and the face of a stranger. By 3 months, almost all infants can distinguish a parent's face from that of a stranger (Nakato et al., 2011). These visual perceptual skills illustrate the highly developed capacities for orienting toward social stimuli that permit infants to participate readily in the social context on which their survival depends.

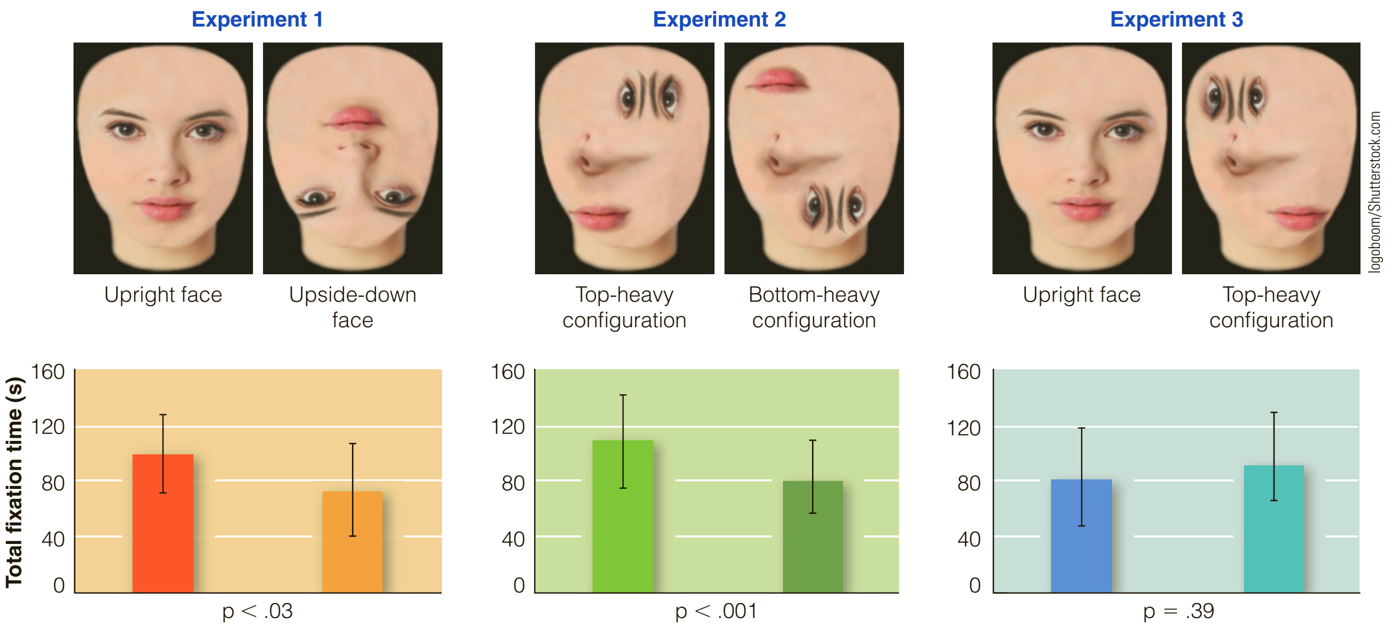
An experiment with newborns who were 25 to 73 hours old demonstrated that one aspect of a face that is important to babies is the top-heavy configuration of the features (Cassia, Turati, & Simion, 2004). FIGURE 5.3 ▶ shows the comparisons that support this conclusion. Babies preferred the upright to the upside-down face and the top-heavy scrambled face to the bottom-heavy scrambled face. By 6 or 7 months of age, infants treat **faceness** as a special visual category, showing surprise when facial features are disorganized or upside down (Cashon, 2011).

In addition to the form, shape, and movement of the human face, certain facial expressions appear to have meaning to very young babies. One- and 2-day-old babies are able to discriminate and imitate the happy, sad, and surprised expressions of a live model. This very early capacity for imitation wanes and is replaced between the ages of 1 and 2 months with a voluntary capacity for imitation of facial expressions when the model is not present. Sometime between 4 and 7 months, infants are able to recognize and classify some expressions such as happiness, fear, and anger (DeHaan & Carver, 2013; McClure, 2000).

Lack of motion in an adult face has a disturbing effect on infants. When adults pose with a still face, babies stop looking at the adult and, in some cases, begin grimacing or showing other signs of discomfort. This reaction suggests that infants anticipate a certain normal sequence of facial movements in a human interaction. The absence of facial movements is not simply noted as novel, but distressing (Adams, Franklin, Nelson, & Stevenson, 2010; Muir & Lee, 2003).

Of course, sights and sounds typically go together. When people speak, their mouths change shape and their faces move. By 3 months of age, infants recognize familiar voice-face associations. They show surprise when a familiar face is paired with an unfamiliar voice (Brookes et al., 2001). So while babies are making sense of their visual environment, they are also using vision as a source of information about language and communication. The visual sense plays a key role in helping babies connect and communicate with others. Through vision, babies are able to recognize their familiar caregivers, observe changes in their caregivers' emotions, and maintain contact through tracking and gazing long before they are able to crawl or walk.

Taste and Smell. Taste and smell are closely linked sensory capacities that contribute to our experience of flavor in food. Although we have only a limited number of taste receptors, possibly five or six, we are able to recognize and differentiate hundreds of different smells. Newborns can tell the difference among sweet,



logoboom/Shutterstock.com

FIGURE 5.3 ▶ STIMULUS PAIRS FROM THREE EXPERIMENTS ON INFANTS' PREFERENCE FOR TOP-HEAVY CONFIGURATIONS For each experiment, the total fixation time toward each stimulus is shown along with the *p* value for comparison between the two stimuli.

Source: From "Can a Nonspecific Bias Toward Top-Heavy Patterns Explain Newborns' Face Preference?" by V. M. Cassia, C. Turati, and F. Simion, 2004, *Psychological Science, 15*, pp. 379–383.

salty, bitter, and sour tastes. Evidence of preference for sweet and salt over bitter and sour can be seen in their facial expressions as well as in the eagerness with which they consume various foods. Certain preferences, especially for sweet and salt, appear to be innate; however, these preferences can be modified as a result of prenatal and early postnatal exposure (Beauchamp & Mennella, 2009).

The food choices a pregnant woman makes influence the flavor of the amniotic fluid. Experiences with these flavors impact a baby's taste preferences. In one study, women were randomly assigned to groups that either drank carrot juice in the last trimester of pregnancy or refrained from eating anything involving carrots. The infants whose mother drank carrot juice showed a clear preference for carrot-flavored cereal in comparison to babies whose mothers did not eat carrots (Beauchamp & Mennella, 2011). Similar studies have demonstrated the impact of taste preferences for anise, mint, vanilla, and blue cheese (Bakalar, 2012).

Taste preferences continue to be influenced by the flavors that are transferred from the lactating mother's diet to her breast milk. Human milk has both nutrients and flavor. Exposure to a variety of smells and tastes through breast milk introduces novelty and diversity of flavor experiences, which result in a greater willingness to eat various foods when babies make the transition from milk to solid foods. The early flavor experiences of breast-fed babies may account for why breast-fed babies have been observed to be less "picky" and more willing to try new foods than formula-fed babies (Beauchamp & Mennella, 2011). These observations suggest a link between very early experiences of taste and smell with later food preferences and the establishment of eating habits (Mennella & Trabulsi, 2012).

In addition to the role of taste in shaping flavor and food preferences, sweet flavors have a pain-reducing impact. In a review of many studies, babies who were given a sweet solution just prior to a painful procedure were compared to babies who had a placebo or no solution. In 93 percent of the studies, babies who received the sweet solution had a much milder response to the pain than did babies in the comparison groups (Harrison, Bueno, Yamada, Adams-Webber, & Stevens, 2010).

The sense of smell plays a role in linking a newborn to his or her mother. Babies recognize the odor of their mother's milk. This familiarity strengthens feelings of comfort and increases the willingness to suck, both of which contribute to the infant's survival (Raimbault, Saliba, & Porter, 2007).

Touch. The skin is the largest sensory organ and the earliest to develop. Touch has a communication function, providing an early form of caregiver–infant interaction. Playful touch, like tickling or tapping, might be used to evoke an infant's smile, whereas holding the baby upright or adjusting their position might have the goal of helping the baby to interact with the environment (Jean, Stack, & Fogel, 2009). Gentle handling, such as rocking, stroking, and cuddling, has soothing effects on a baby. Swaddling—the practice of wrapping a baby snugly in a soft blanket—is a common technique for soothing a newborn across many cultures. One of the effective techniques for caring for low-birth-weight babies is to introduce regular gentle stroking, rocking, and other forms of soothing touch. As mentioned earlier in the chapter, Kangaroo Care exploits the premature infant's sense of touch to stimulate sensory systems and reduce stress.

Touch is an active as well as a passive sense; babies use it to explore objects, people, and their own bodies. Sucking and mouthing are early forms of exploratory touch. Babies can recognize the qualities of objects from the way they feel in their mouths—nubbly or smooth, chewy and flexible, or rigid. For older infants, most tactile information comes through touching with the hands and bringing objects to the face in order to take a closer look or to explore them with the mouth. By 5 or 6 months of age, infants can use their hands for the controlled examination of objects. They finger surfaces to explore small details and transfer objects from one hand to the other to detect corners, shapes, and the flexibility of surfaces as well as the object's size, temperature, and weight (Streri, 2005).

The Interconnected Nature of Sensory/Perceptual Capacities

The sensory/perceptual capacities function as an interconnected system to provide a variety of information about the environment (Calvert, Spence, & Stein, 2004; Murray & Wallace, 2012; Stein, 2012). Listening to a person's voice provides clues to their identity and stimulates an area of the brain that is also associated with face recognition. Research on multisensory perception suggests that the brain integrates information from the various sensory regions

Sucking and mouthing are important ways of exploring objects. Fists and toes are the first easy targets.

to improve recognition and to compensate when one region is impaired or restricted (Rosenblum, 2013).

Consider the situation when an infant is being nursed. At first, the mother guides the baby toward her breast, but the baby makes use of vision, touch, smell, and movement to find and grab hold of the nipple. If very hungry, the baby may close the eyes in order to concentrate exclusively on bursts of sucking behavior, coordinating sucking and swallowing as efficiently as possible. But as the initial swallows of milk satisfy strong hunger pangs, the baby pauses to take in other aspects of the situation. The baby may then gaze at the contours of the mother's face, playfully lick the milk dripping from the mother's breast, smell the milk's fragrance, taste its special sweet taste, and listen to the sound of the mother's voice offering comfort or inviting conversation. The baby may reach up to explore the mother's skin or relax in the comfort of the mother's gentle embrace. All the sensory information becomes integrated to create familiarity with this experience, including a growing recognition of the mother and a rich mixture of sensory impressions associated with this special situation in which hunger is satisfied.

The sensory/perceptual regions of the brain show evidence of integration in infancy, providing essential adaptive benefits for attention, recognition, and appropriate behavioral responses. This sensory integration improves with age, with optimal functioning achieved at around age 15 (Burr & Gori, 2012). Given the multimodal nature of most complex cognitive tasks, it is not surprising that multisensory integration deficits have been associated with various neurodevelopmental disorders, especially dyslexia and attention deficit disorder (Dionne-Dostie, Paquette, Lassonde, & Gallagher, 2015).

FURTHER REFLECTION: *Describe some examples of how hearing, vision, touch, and smell work together to help infants form schemes about their world. Imagine that one of these senses was impaired, vision or hearing, for example. How might the other senses fill the gap as an infant strives to gather information about his or her world?*

Motor Development

Motor development refers to all the changes in a child's ability to control and direct movement, including movement of the eyes and head, as well as movement of fingers, arms, legs, and torso. Movement is involved in just about every aspect of observable behavior, from a smile or grimace to arm waving and leg kicking. Motor development begins during the prenatal period as the fetus twitches, hiccups, waves its arms, kicks its legs, sticks out its tongue and orients its body within the amniotic fluid. These prenatal movements lay the groundwork for neural pathways that will eventually sustain more coordinated movement after birth.

Many of the observable early motor behaviors are **reflexes**, meaning that a specific stimulus evokes a particular motor response without any voluntary control or direction. Reflexes are thought to have an evolutionary origin, linking humans to their mammalian ancestors. They help infants survive and provide a platform upon which they develop more complicated sequences of voluntary behaviors. The sucking reflex is a good example. At birth, inserting something in an infant's mouth produces a sucking reflex. This helps infants gain nourishment relatively easily before sucking behavior is under their voluntary control. Before long, infants become skillful at controlling the strength and sensitivity of sucking behavior. They also use sucking and mouthing as strategies for exploration. Infants use their mouths to explore objects that they can then identify visually, thus transferring information from the sense of touch to the visual sense.

Table 5.2 describes a number of common infant reflexes, the evoking stimulus, and the response. Infant reflexes include sucking, grasping, rooting (turning the head in the direction of the cheek that is stroked), coughing, and stepping. With time, many of these behaviors make a transition from an involuntary to a voluntary behavior. Eventually infants blend several of these new movements into increasingly coordinated and complex patterns. Reaching and grasping is a good example.

Reaching and Grasping. In the first weeks of life, we see a strong, involuntary grasp reflex. If you put something, like a finger or a rattle handle in a baby's hand, the hand closes tightly. Over time, this involuntary reflex is transformed into purposeful, goal-directed reaching and grasping. Advances in reaching and grasping result from an ongoing interaction among sensory and perceptual abilities, motor skills, cognitive capacities, social interactions, and cultural contexts (Diamond, 2007). Infants practice controlled, coordinated muscle movements, guided by visual and auditory cues—particularly cues about size, distance, and direction.

In the first few months of life, babies cannot achieve much in the way of voluntary reaching because they cannot yet keep their head up or their torso from collapsing. When babies are propped up in an infant chair, you may observe them wave their arms and shake their hands in the direction of an object. At first, this arm flapping and waving is not connected to the goal of reaching for a toy. But over time, as the shoulder and elbow become more developed, and as the arm waving results in reaching a toy, the frequency and stability of hand–toy contact improves. By the time they are able to sit independently, they also begin to show evidence of coordinated reaching, grasping, and handling objects. They make a large movement in the direction of the object and then modify their hands in order to grab hold of the object. Between 5 and 7 months, babies become increasingly accurate at reaching and grasping a moving object, anticipating the direction of its movement, and alternating their hands to intercept it (Adolph & Robinson, 2015; Robin, Berthier, & Clifton, 1996; Rochat, 1989).

By 12 months, babies have mastered the pincer grasp, using their index finger and thumb to pick up tiny things, such as string and thread, pieces of dry cereal, and spaghetti noodles. With this advance, they can also manipulate things by lifting latches, turning knobs, and placing small things inside bigger things and trying to get them out again. These motor skills provide new information about how objects work and how they relate to one another. The development of fine motor skills contributes to the

Table 5.2 Some Infant Reflexes

Reflex	Evoking Stimulus	Response
Reflexes that facilitate adaptation and survival		
Sucking reflex	Pressure on lips and tongue	Suction produced by movement of lips and tongue
Pupillary reflex	Weak or bright light	Dilation or constriction of pupil
Rooting reflex	Light touch to cheek	Head movement in direction of touch
Startle reflex	Loud noise	Similar to Moro reflex (below), with elbows flexed and fingers closed
Swimming reflex	Neonate placed prone in water	Arm and leg movement
Reflexes linked to competences of related species		
Creeping reflex	Feet pushed against a surface	Arms and legs drawn under, head lifted
Flexion reflex	Pressure on sole of foot	Involuntary bending of leg
Grasp reflex	Pressure on fingers or palm	Closing and tightening of fingers
Moro reflex	Infant lying on back with head raised—rapidly release head	Extension of arms, head thrown back, spreading of fingers, crossing arms across body
Springing reflex	Infant held upright and slightly forward	Arms extended forward and legs drawn up
Stepping reflex	Infant supported under the arms above a flat surface	Rhythmical stepping movement
Abdominal reflex	Tactile stimulation	Involuntary contraction of abdominal muscles
Reflexes of unknown function		
Achilles tendon reflex	Blow to Achilles tendon	Contraction of calf muscles and downward bending of foot
Babinski reflex	Mild stroke on sole of foot	Fanning and extension of toes
Tonic neck reflex	Infant on back with head turned to one side	Arm and leg on side toward which head is facing are extended, other arm and leg flexed

© Cengage

infant's sense of mastery and can be a source for positive emotions. At the same time, they may cause new conflicts between the baby and the caregiver, who knows that tiny things shouldn't go into the mouth, and that certain objects ought not to be touched, moved, and manipulated.

Motor Milestones

Motor skills develop as a result of physical growth and maturation in combination with perceptual information and opportunities for exploration of the environment. The infant's drive to explore and master the environment as well as encouragement from caregivers contribute to the rate and sequence of motor development (Adolph & Robinson, 2015). Table 5.3 lists the milestones of motor development and a typical sequence of accomplishments during the first year of life. Usually, during the first 12 months, babies begin to hold their heads up and roll over by themselves; they learn to reach for things and grasp them; they sit, crawl, stand, and walk.

However, research has documented substantial variability in the sequence and rate at which infants acquire these skills. Individual children grow in spurts, interspersed with times of slow growth and some periods of regression (Adolph, Berger, & Leo, 2011). Not all children crawl before they walk. Some scoot along on their bottoms; others slide or slither on their tummies. Children in some cultures sit, stand unassisted, and walk at a much younger age than in other cultures. Parental expectations and the ways parents treat their babies, including the ways they massage, stretch, or exercise them, seem to influence the timing of the onset for some of these milestones (Adolph & Berger, 2011).

During the second year, walking becomes increasingly steady. Crawling may be used for play but is no longer the preferred method for locomotion. One might wonder why babies give up the stable, well-developed strategy of crawling for the more shaky, precarious approach of walking. Several explanations seem relevant. First, a social explanation suggests that babies recognize that all the older adults around them are walking. And they receive social encouragement for walking. In addition, as they gain the skills of walking, they can cover ground more quickly, engage in exploration with objects further away, and encounter different kinds of social interactions (Adolph & Tamis-LaMonda, 2014). During the second year, babies explore stairs, climbing up and down using a variety of strategies. They start to slide or jump down from modest heights. Each of these accomplishments requires practice, refinement, struggle, and, finally, mastery (Adolph et al., 2012).

Table 5.3 Motor Development Milestones—First 24 months

1 Month	3 Months	4–7 Months	8–12 Months	12–24 Months
• Strong reflex movements • Makes jerky, quivering arm thrusts • Brings hands within range of eyes and mouth • Moves head from side to side while lying on stomach • Head flops backward if unsupported • Keeps hands in tight fists	• Raises head and chest when on stomach • Stretches and kicks on back • Opens and shuts hands • Brings hand to mouth • Grasps and shakes toys	• Rolls both ways • Sits with and without support of hands • Supports whole weight on legs • Reaches with one hand • Transfers object from hand to hand • Uses raking grasp	• Gets to sitting position without help • Crawls forward on belly • Assumes hands-and-knees position • Gets from sitting to crawling position • Pulls self up to stand • Walks holding onto furniture	• Walks alone • Pulls toys behind her while walking • Carries large toy or several toys while walking • Begins to run • Stands on tiptoe • Kicks a ball • Climbs onto and down from furniture unassisted • Walks up and down stairs holding onto support

The Contributions of Nature and Nurture in Motor Development

Motor development provides an excellent illustration of the interaction between the genetically guided plan for growth and experience. The unfolding of motor capacities is guided by genetics, beginning as it does with the presence of a wide range of reflexes that are hardwired, so to speak, into the infant's neurological system. At the same time, within this plan, one observes both individual and group differences. Not only are babies different from one another at birth, but they also show different rates of motor advancement. For example, one study examined how babies adapted their locomotor strategy for going down a slope. Thirty-one infants, all 14 months old, were recruited for the study. Even though they were all the same chronological age, their prior experience with walking ranged from 10 days to 137 days (Adolph & Eppler, 2002).

In addition to individual differences in the timing and tempo of motor development, cultures differ in the opportunities provided for motor exploration. In a longitudinal study of almost 16,000 infants living in the United Kingdom (England, Wales, Scotland, and Northern Ireland), cultural differences in the attainment of motor milestones were noted. Black Caribbean infants, Black African infants, and Indian infants were on average more advanced in motor development than White infants. Advantages of the babies of Caribbean, African, and Indian ethnicity could not be accounted for by financial factors. A combination of parental expectations and parenting practices associated with cultural tradition, such as holding the babies upright, stretching and massaging their legs, helped support advanced motor development in these groups (Kelly, Sacker, Schoon, & Nazroo, 2006).

Researchers now regard the regularities in motor behavior as a result of a dynamic process in which infants coordinate their physical actions with the demands and opportunities of the situation and the expectations of the culture. The combination of a maturing central nervous system, growth in strength and coordination, opportunities for various types of movements, and the emergence of cognitions to understand and anticipate actions underlies an ongoing process of self-correcting, adaptive movement (Adolph, 2008). Perception and action work hand in hand, giving the infant information about the physical properties of the situation and feedback about the consequences of a specific motor strategy. Over time and with practice in similar situations, infants discover the combination of action, intensity, direction, and speed that will create the desired outcome. With additional practice, this pattern becomes most likely and increasingly efficient (Thelen, 1995). (See the **Applying Theory and Research to Life** box on the stepping reflex.)

Most babies reach a point when they rock in a stationary position on all fours before they can crawl. In repeated observations of 15 infants, they first showed a clear hand preference before they made the transition to crawling. When infants fell from a seated position onto their hands, they tended to fall onto their non-preferred hand, so that the preferred hand was available to reach out and begin crawling. Confidence in being able to maintain one's body weight on one arm and two legs while reaching out with the preferred hand is part of the motor sequence necessary for forward crawling (Adolph, Vereijken, & Denny, 1998; Goldfield, 1989). What is more, in a systematic observation of crawling, it appears that infants intersperse crawling with sitting. After short bouts of crawling, they typically turn to a sitting position, possibly to rest or to reorient themselves in space before moving on (Soska, Robinson, & Adolph, 2015). This observation illustrates how new behaviors may emerge from or build upon earlier milestones. Crawling, which tends to be regarded as natural and easily performed in infancy, is in fact achieved by long and patient effort in the coordination of head and shoulder movement, reaching, and kicking. As the baby changes from crawling to walking, new strategies for navigating the environment have to be invented.

Infants gain greater motor control with each motor milestone from sitting and crawling to standing and walking. At the

APPLYING THEORY AND RESEARCH TO LIFE

The Dynamic Development of Stepping

At some point within the first 2 or 3 weeks of life, when you hold an infant upright under the arms, the infant makes stepping motions that look very much like walking (Barbu-Roth et al., 2009). This stepping response is evoked by a number of stimuli, including the posture in which the baby is held, tactile stimulation to the feet, and visual information about the relationship of the body to the surface below. By the age of 2 or 3 months, this stepping behavior seems to disappear. Initial explanations for this loss of the stepping response were that the reflex is inhibited by higher level cortical functions. The assumption was that the stepping reflex was a vestigial behavior from some earlier evolutionary primate period, and that true stepping and walking were products of voluntary movement genetically programmed to emerge with more advanced cortical development.

The idea that a behavior that is so closely related to walking would disappear and then reappear was puzzling. Esther Thelen and Donna Fisher (1982) designed research to examine the relationship of the biomechanics of infant stepping and its relation to the infant's posture and physical growth. They used video recordings and electromyography (EMG) of four muscle groups to capture data on patterns of muscle activation associated with various movements. Their first goal was to explore the similarities between infant stepping while held upright and infant kicking while the infants were lying on their backs. The former seems to disappear and the latter becomes stronger and more coordinated over time. Their second goal was to consider the biomechanical conditions that might constrain the stepping response and increase the kicking response.

The infants who participated in the study were all under 2 weeks old. Of 13 infants, 8 showed both stepping and kicking during the recording session. Both the stepping and kicking showed alternating right- and left-leg action. The EMG data (an electronic technique for recording muscles at rest and when they are contracting) for the two types of movement were quite similar. The timing of the flexion and extension phases of the kick and the step were also similar. Thelen and Fisher argued that neonatal stepping and kicking while lying on the back are essentially the same movement patterns.

The key to the disappearance of stepping and the increase in kicking is in the role of gravity as infants' legs gain mass. As the legs gain in fat, the muscle strength needed to lift the legs against the force of gravity is not sufficient to permit the stepping action. However, in the prone position, the kicking action is actually supported by the force of gravity. During the first months of life, the growth of body fat outpaces the growth of muscle mass, so the babies cannot lift their legs in the upright position. However, the action itself is not lost and in fact is practiced actively when babies are lying down. When slightly older babies were submerged waist-high in water, overcoming the constraints of body mass and gravity, the stepping pattern was observed (Thelen, Fisher, & Ridley-Johnson, 1984). Thus, the shift from stepping to no stepping was actually a dynamic adaptation to the combination of changing physical characteristics in a particular physical context (Thelen & Smith, 1994).
The results of this research led to a transformation in the way we think about motor development. Studies of infant care in other cultures, especially in Africa and Central America, find a more common practice of holding infants upright rather than laying them down in a cradle or crib. Infants in these cultures have been observed to walk at an earlier age than Western infants. Thelen and Fisher suggested that infants who are given more experience in an upright position strengthen their leg muscles, leading to an earlier use of legs for support in standing and walking.

Rayes/Digital Vision/Jupiter images

According to research on motor development, the stepping reflex remains intact and plays a role in upright walking when babies are strong enough to lift their legs against the force of gravity.

Critical Thinking Questions

1. Explain how this research on stepping significantly altered our understanding of motor development.
2. Describe the interactions of neurological, physical, and experiential aspects of motor behavior that are illustrated in this research on stepping.
3. Apply the principles of development illustrated in this research to other examples of behaviors that might be better understood from a dynamic systems perspective.

same time, each new motor capacity permits the exploration of a more varied environment. As a result, infants have to be able to make immediate assessments of the relationship between their physical abilities and the environmental conditions in order to decide whether to avoid action, take familiar actions, or try to invent some new, adapted action. The evidence for this flexibility can be seen as babies experiment with descending slopes and slides. Some try going headfirst and then slide backwards; others try to go down with a crablike crawl and then switch over to their bottoms; and still others won't go down at all (Adolph & Eppler, 2002). Infant motor behavior requires flexibility because of the rapid changes in physical size and strength and the variety of contexts for movement.

FURTHER REFLECTION: *Summarize the contributions of each of the motor milestones to the infant's ability to explore the environment and enter into the social life of the family.*

Sensorimotor Intelligence: Processing, Organizing, and Using Information

OBJECTIVE 3 Describe the development of sensorimotor intelligence, including an analysis of how infants process information, organize experiences, conceptualize causality, and understand the properties and functions of objects.

What is sensorimotor intelligence? Think for a moment of a familiar experience, such as tying your shoelaces. The pattern of tying shoelaces unfolds with little, if any, language involved. In fact, the task of explaining to a young child how to tie shoelaces is particularly difficult because very few words or concepts are part of the process. This kind of motor routine is an example of **sensorimotor intelligence**.

According to Piaget's (1970) theory of cognitive development that was introduced in chapter 2, the growth of intelligence during infancy is based on **sensorimotor adaptation**. From the very earliest days of life, infants use their reflexes to make contact with the environment. At the same time, they gradually alter their reflexive responses to take into account the unique properties of objects around them. When infants adapt their sucking reflex to make it more effective, or when they use different techniques of sucking on the breast and the bottle, they are demonstrating sensorimotor intelligence. The familiar scheme for sucking is modified so that it takes into account the special properties of the breast and the bottle, depending on the situation.

Infants do not use the conventional symbolic system of language to organize experience. Rather, they form concepts through perception and direct investigation of the environment. Sensorimotor intelligence encompasses the elaboration of patterns of movement and sensory experiences that the infant recognizes in association with specific environmental events. In the sections that follow, we will describe the infant's information- processing abilities, their emerging ability to understand causality, and their approach to exploring and categorizing objects.

Information-Processing Abilities

Whereas Piaget emphasized the process of sensorimotor exploration and adaptation, other theorists incorporate evidence from neuroscience to explain how development of the central nervous system constrains or facilitates cognitive functioning. As children get older, they can keep more information in the mind at once, thereby allowing them to organize, coordinate, and compare data in order to solve problems (Case, 1998; Morra, Gobbo, Marini, & Sheese, 2008; Young, 2011).

Four basic information-processing abilities provide the cognitive resources that support the maturation of sensorimotor intelligence. They include attention, processing speed, memory, and representational abilities (Rose, Feldman, & Jankowski, 2009).

Attention refers to the infant's ability to focus on an object or task as well as to shift or redirect focus from one object or task to another. Attention is a foundational cognitive ability that allows infants to follow the gaze of another person, track the path of a moving object, and participate in alternating interactions. Attention is typically measured by noting how long an infant looks at an object and how often the infant shifts gaze from one object to another when comparing objects. Problems in attention can be early signs of developmental delay. For example if the 1-month-old baby does not track an object as it moves from side to side and this inability to track moving objects continues into the second or third month, caregivers are advised to contact their pediatrician (American Academy of Pediatrics, 2014).

Processing speed is the time it takes to identify a stimulus and figure out its meaning. The faster the processing speed, the more quickly one can incorporate a stream of information. Processing speed is often assessed with reaction time tasks. The time elapsed from presentation of the stimulus to response is taken as evidence of processing speed.

Memory is a complex capacity that includes recognizing something as similar to something one has seen or experienced in the past, holding information in mind for a brief period before using it and recalling information as needed (Flom & Bahrick, 2010). One way of studying memory in infancy is through the use of habituation tasks. Memory is inferred from an infant's ability to compare a stimulus with something that was experienced in the past.

Representational skills are those cognitive abilities that allow a child to let one thing stand for something else. Representational skills are involved when a child uses a word or a gesture to indicate an object or when a child pretends, such as when using a block to feed a doll or giving it a sip of pretend water from a pretend cup. The idea is that the child has a mental image or representation of an object or action, and the child is able to work with this image, expressing it in words, actions, or pretense.

Taken together, these information-processing skills—attention, processing speed, memory, and representational skills—support an infant's ability to form increasingly complex schemes about objects, people, actions, and the relationships among them. Changes in the demand properties of one aspect of a task, such as processing speed or memory, may influence attention or representational competence. For example, immature memory capacities may make it difficult for infants to accurately represent and categorize new objects (Oakes, 2009).

According to an emerging view, sometimes referred to as the *theory theory*, infants form theories about how their world operates and modify these theories as new information is gathered (Wellman, 2014). The infant starts out with some basic sensory, motor, and cognitive organizational structures. With new information, a process of adaptation results in the revision of basic schemes to better predict and interpret experience (Xu & Kushnir, 2013). For example, Ruby, who is 12 months old, may be surprised and upset when her grandmother scolds her as she reaches for a shiny glass bowl on the table. Grandmother knows that the bowl will break if Ruby pushes it off the table. By 16 months, Ruby warily watches her grandmother's face as she reaches for the bowl and may withdraw her hand if she sees Grandma frown or hears the sharp "No!" that has come to be associated with "Don't touch." Ruby has developed a theory that she should not touch the bowl, which she cautiously tests by reaching for it and watching for the response.

Causal Schemes

One of the most important components of sensorimotor intelligence occurs when infants make things happen. Causal schemes refer to the capacity to anticipate that certain actions will have specific consequences. Infants develop an understanding of **causality** based largely on sensory and motor experiences. By 9 months of age, infants show evidence that they anticipate the direction of an action, like pouring a liquid into a glass or using a spoon to bring soup to the mouth, and are surprised when the action is not completed or takes an unexpected twist. This understanding leads to goal-directed behavior; infants become increasingly intentional and purposeful in their behaviors (Reid et al., 2009). Babies discover that if they cry, Mama will come to them; if they kick a chair, it will move; and if they let go of a spoon, it will fall to the floor. These predictable sequences are learned through repetition and experimentation. The predictability of the events depends on the consistency with which objects or people in their world respond as well as on the child's initiation of the action. Babies learn to associate specific actions with regularly occurring outcomes. They also experiment with their own actions to determine the variety of events that a single behavior may cause. Eventually, they are able to work backward: They can select a desirable outcome and then perform the behavior that will produce it.

The achievement of complex, purposeful, causal behaviors develops gradually during the first 2 years of life. The dynamic process of establishing a complex causal scheme is illustrated in a study of the emergence of the use of a spoon as a tool for eating (Connolly & Dalgleish, 1989). Infants were observed once a month for 6 months in their home during a mealtime. At first, actions involving the spoon appeared to focus on exploration of the spoon itself. The infants banged the spoon, sucked it, or rubbed it in their hair. Then the babies showed an understanding of the purpose of the spoon as a tool by repeating the action sequence of dipping the spoon in the dish and bringing it to the mouth. However, no food was on the spoon. In the third phase, babies began to integrate the function and the action by loading the spoon with food and then bringing it to the mouth. During this phase, they made so many errors that very little food actually got to the mouth via the spoon. Finally, babies were able to coordinate the action and the function by using the other hand to steady the bowl, altering the angle of the spoon, picking up food they had dropped, and devising other strategies to enhance the function, depending on the type of food involved. Here we see a demonstration of how one complex motor behavior becomes part of a problem-solving action sequence during the sensorimotor period of development.

Piaget and Inhelder (1966/1969) described six phases in the development of **causal schemes** (see Table 5.4). In Phase 1, *reflexes*, cause and effect are linked through the involuntary reflexive responses. The built-in stimulus-response systems of key reflexes are viewed as the genetic origin of intelligence. Babies suck, grasp, and root in response to specific types of stimulation. Piaget viewed these reflexes as adaptive learning systems. In detailed observations of his youngest child, Laurent, he noted daily changes in sucking behavior during the first month of life. Laurent became increasingly directed in groping for the breast, forming early associations between those situations in which he would be fed and those in which he would not (Piaget, 1936/1952).

Table 5.4 Six Phases in the Development of Sensorimotor Causality

Phase	Approximate Age	Characteristic	Example
1. Reflexes	From birth	Reflexive responses to specific stimuli	Grasp reflex
2. First habits	From 2nd week	Use of reflexive responses to explore new stimuli	Grasp rattle
3. Circular reactions	From 4th month	Use of familiar actions to achieve new goals	Grasp rattle and make banging noise on table
4. Coordination of means and ends	From 8th month	Deliberate use of actions to achieve new goals	Grasp rattle and shake to play with dog
5. Experimentation with new means	From 11th month	Modifications of actions to reach goals	Use rattle to bang a drum
6. Insight	From 18th month	Mental recombination of means and ends	Use rattle and string to make a new toy

© Cengage

In the second phase, *first habits*, the reflexive responses are used to explore a wider range of stimuli. Babies explore toys, fingers, parents' noses, and blankets by sucking on them. Gradually, they discover the unique properties of objects and modify their responses according to the demands of the specific objects. The fact that a baby can satisfy the need to suck by bringing an object to the mouth is a very early form of purposive causal behavior.

The third and fourth phases involve coordination of means and ends, first with familiar situations and then with new ones. In the third phase, *circular reactions*, babies connect an action with an expected outcome. They shake a rattle and expect to hear a noise; they drop a spoon and expect to hear a noise when it hits the floor; they pull Daddy's beard and expect to hear "ouch." They do not understand why a specific action leads to the expected outcome, but they show surprise when the expected outcome does not follow.

In the fourth phase, *coordination of means and ends*, infants use familiar actions or means to achieve new outcomes. They may shake a rattle to startle Mommy or pull Daddy's beard to force him to look away from the television set. The means and the outcomes have become quite distinct. There can be no question about the purposiveness of behavior at this point. At this stage, coordination of means and ends are closely tied to a specific context. For example, a baby may know how to make certain kicking motions to move a mobile or to get a toy to jiggle in the crib. But in another room with the same toy, the baby may not make the same connection. This may explain why babies perform less competently in the laboratory environment than they do at home. Many causal strategies that become part of a baby's daily repertoire are supported by the context of a familiar environment (Baillargeon, 2004, 2008).

The fifth phase, *experimentation with new means*, begins as children experiment with familiar means to achieve new goals. When familiar strategies do not work, children will modify them in light of the situation. One can think of this stage as sensorimotor problem solving. Children will try to reach a drawer by standing on a box, fix a broken toy with a string, or make a gift by wrapping a toy in a piece of tissue.

The last phase in the development of sensorimotor causality, *insight*, involves mental manipulation of means–end relationships. Instead of actually going through a variety of physical manipulations, children carry out trial-and-error problem-solving activities and planning in their minds, anticipating outcomes. They can sort out possible solutions and reject some without actually having to try them. The result is insight: Mental experimentation brings the child to the best solution, which is the only one necessary to enact.

The capacity to perceive oneself as a causal agent and to predict the outcome of one's actions are essential to the development of a sense of competence, which involves investigation of the environment, directed problem solving, and persistence toward a goal. At later stages, the abilities to formulate a plan, execute it, and evaluate its outcome depend on these skills.

Understanding the Nature of Objects and Creating Categories

Babies are active explorers of their environment (Bruner, 2001). From birth, they track objects visually, altering their gaze to maintain contact with them. As they get older, they use combinations of mouthing, looking at, and manipulating objects as a type of exploratory behavior that provides infants with a scheme for gathering information about novel objects (Diamond, 2007). As products of this active engagement with the object world, two related but independent aspects of infant intelligence develop: an understanding of the nature of objects, and the ability to categorize similar ones.

The Nature of Objects.

Through looking, manipulating, and examining, infants establish that objects have basic properties. In the discussion of vision, we pointed out that very young babies recognize the contours of objects and that by 4 months they seem to perceive objects just as adults would. That is, babies see objects as separate from each other, defined by boundaries, taking up space, having depth, and having certain attributes of weight, color, malleability, texture, and the capacity to contain something else or not. All these properties influence the types of actions that infants use to explore the objects and the ways they are eventually woven into other actions (Xu, 2003).

Object Permanence. Piaget (1954) argued that understanding the properties of objects was one of the foundations of logical thought. One of the most carefully documented of these properties is **object permanence**—the concept that objects in the environment are permanent and do not cease to exist when they are out of reach or out of view. A permanent object retains its physical properties even when it cannot be seen.

Piaget suggested that initially, the infant is aware of only those objects that are in the immediate perceptual field. If a 6-month-old girl is playing with a rattle, it exists for her. If the rattle drops

Courtesy of Philip Newman

Through mouthing and grasping, Olivia is exploring the fuzzy blanket.

out of her hand or is taken away, she may show some immediate distress but will not pursue the rattle. The attainment of the concept of the permanent object frees children from reliance on only what they can see. The ability to hold the image of an object in the mind is a critical step in the emergence of complex representational thinking.

Piaget suggested that the capacity to understand that objects continue to exist requires a level of representational or symbolic thinking that would permit an infant to hold the idea of the object in mind while it was hidden. It also requires a combination of sensorimotor capacities that permit the infant to become actively engaged in reaching, tracking, and uncovering hidden objects and learning about the spatial properties of objects in the environment. Thus, according to Piaget, the first real evidence that infants have the ability to pursue a hidden object could not really be observed much before 8 or 9 months of age when babies begin to crawl, and the full confidence in an object's permanence could probably not emerge much before 16 to 18 months when infants have access to representational thinking. By this age, infants can imagine various movements and displacements of objects without actually viewing them.

A growing body of research has focused on what infants know and expect about objects well before they can crawl or pursue objects through space. In a series of experiments, Renée Baillargeon (2008) has tried to determine how infants evaluate objects that are hidden from view. One of the features of her experiments is that she has deleted the motor search component that is required in Piaget's studies of object permanence. Most of her experiments use habituation in pretest conditions and a change in looking time as evidence for infants' reactions to an unexpected outcome. At very early ages, before infants can search for and retrieve objects, they appear to have a memory for the locations of objects. Infants can follow an object through at least three different ways of hiding it: by placing the object in a container, by moving the object behind a screen, or by covering the object (Baillargeon, 2004).

Young infants have a well-developed sense of objects as distinct, permanent structures that will be set into motion when they are pushed, knocked, or launched in some other way by another object. They also expect that, once in motion, an object will follow a prescribed trajectory (Belanger & Desrochers, 2001). The infant's ability to anticipate an object's trajectory behind a screen is an early step in a sequence of abilities that will produce the complex search process that Piaget described.

The Categorization of Objects. Physical objects have basic properties:

1. Objects have a location and a path and speed of motion.
2. Objects have mechanical properties that include how they move and their relation to other objects.
3. Objects have features, such as their size, shape, and color.
4. Objects have functions; this is what objects do or how they are used (Wilcox, Schweinle, & Chapa, 2003).

As infants explore and experiment with objects, they begin to devise schemes for grouping objects together. They modify these schemes to add new items to the category and to differentiate one category from another. Categories can be based on the physical properties of objects, such as smooth and rough, or on the functions of objects, as in something to sit on and something to dig with. The classification of objects and events into categories is one method infants have for coping with the array of new experiences they encounter.

Categorization is an aid to information processing. By treating certain individual objects as similar because they belong to the same basic grouping, like two individual red blocks or two wiggly goldfish, the potential amount of information to process is reduced. Categories can be specific, such as cups, chairs, and cars, or abstract, such as tools, food, or animals. If an item is classified as a member of a category, then all the information that has been accumulated regarding that category can automatically be applied to the specific object. This process aids in the storage and recall processes of memory, in reasoning and problem solving, and in the acquisition of new information. Classification of objects into categories is a cognitive capacity that becomes increasingly sophisticated over the childhood years.

One category that has special meaning for infants is *faceness*. By 6 months of age, infants attribute clear expectations to faces. They expect faces to be organized in certain patterns and to move and respond in special ways. Six-month-old infants can categorize faces as attractive or unattractive (Zebrowitz, Bronstad & Montepare, 2010).

A second related category is the distinction between people and inanimate objects (Atkinson, Heberlein, & Adolphs, 2010; Rakison & Poulin- Dubois, 2001). Infants have been observed to smile, vocalize, and become more active when interacting with people as compared to things. By 3 months of age, infants show their ability to categorize stimuli as people or things by smiling almost exclusively at people. Infants may look with equal interest at inanimate objects, especially novel ones, but their smiles are reserved for people. This distinction between the social and the nonsocial realm can be considered a **foundational category**. It provides evidence for the unique role of social relationships in the process of adaptation and growth. From this basic distinction between a person and a thing, many further categories, such as father and mother, familiar and stranger, or adult and child, emerge that begin to differentiate the infant's social world.

Research on infant categorization skills typically involves sorting objects or images into groups. Using a habituation-type methodology, the earliest form of categorization can be observed. When 4.5-month-old babies see an object alone and then placed next to a different object, they respond in a way that indicates their recognition that the two objects are different (Needham, 2001). Using visual silhouettes, 3- and 4-month-old babies were able to distinguish between images of cats and dogs, primarily through a comparison of the information in the shape and features of the silhouette heads (Quinn, Doran, Reiss, & Hoffman, 2009; Quinn, Eimas, & Tarr, 2001). Thus, at very early ages, infants are able to differentiate and group people and objects in their environment.

The categorization process advances over the first 24 months as features of objects are differentiated and linked to concepts and functions. Information about the shape and size of objects seems to guide an infant's identification and categorization of objects by 4.5 months. At 7.5 months, infants make use of information based on differences in pattern, and by 11.5 months they incorporate color and shininess as features that help guide categorization (Woods & Wilcox, 2010).

By 15 months, babies will touch all the objects that belong to one category and then touch all the objects in another category. By 18 months of age, children can perform multidimensional categorization tasks (e.g., sorting eight objects, such as four brightly colored yellow rectangles and four human-shaped plastic figures, into two distinct groups) (Gopnik & Meltzoff, 1987, 1992, 1997). This kind of sorting does not require the ability to give names to the objects. However, by 20 months, infants will use both visual cues and names to categorize objects. The larger the infant's vocabulary, the more likely the baby is to use names to help group objects together (Nazzi & Gopnick, 2001). Thus, categorizing and naming appear to be closely linked. By the close of the second year of life, babies know that objects have certain stable features, that some objects belong with others, and that objects have names. With these achievements, infants impose a new degree of order and predictability on their daily experiences.

The Prefrontal Cortex and Infant Intelligence

The cognitive skills that we have described in the preceding sections—causal schemes, object permanence, and the categorization of objects—are all evidence of a capacity to generalize principles and devise abstract rules from experience. One hallmark of human intelligence is the ability to derive abstract concepts, rules, and generalizations from sensory and motor experiences and to apply them in new situations. The area of the brain that appears to be responsible for supporting these capacities is the **prefrontal cortex**.

The prefrontal cortex is more developed in humans than in other species, and, within humans, continues to develop into the mid-20s. It has been viewed as the brain's executive, an area of the brain that is highly interconnected with all the sensory and motor systems and with areas of the brain associated with emotion, memory, and reward (Kolb et al., 2012; Miller, Freedman, & Wallis, 2002). The neurons in the prefrontal cortex can be activated from all the sensory domains in anticipation of events, during actions, and during memory of past events.

One of the key features of neurons in the prefrontal cortex is their ability to sustain mental activity for several seconds without additional stimulation. As a result, the neurons of the prefrontal cortex are able to guide actions for the period of time it takes to transmit signals to other related brain areas in order to accomplish a task. This longer "hold" time also plays a role in the ability to delay responses and resist distractions. From 6 to 12 months, infants perform increasingly better on tasks that require them to resist distractions (Holmboe et al., 2010).

Neuroimaging studies of infants find that the prefrontal cortex is involved in language processing, identification of novel stimuli, working memory, goal-oriented reasoning, and categorization of objects. Studies of the neurodevelopment of categorization suggest that the lower brain regions, especially the basal ganglia, are involved in the recognition of individual stimuli and related responses. The prefrontal cortex links the details of these individual experiences together to form general representations. After repeated exposure, the prefrontal cortex plays a leading role, recognizing individual stimuli as examples of more general categories and associating them with appropriate responses (Antzoulatos & Miller, 2014; Seger & Miller, 2010).

There are both benefits and costs to the long maturational time and plasticity of the prefrontal cortex. The neural connections and pathways within the prefrontal cortex as well as from the prefrontal cortex to other areas of the brain can be shaped by many environmental factors, both prenatally and over the course of childhood and adolescence. The early years of synaptic production in the prefrontal cortex establish a structure upon which subsequent cognitive, affective, and social adaptation are based. Rich sensory and motor stimulation, comforting touch, responsive parenting, and opportunities for peer play are all examples of early experiences that are known to have beneficial consequences for the formation of neural development in the prefrontal cortex. However, the sensitivity of the prefrontal cortex to environmental conditions also contributes to vulnerability when the infant or young child is exposed to disruptive factors including sensory deprivation, stress, harsh handling, and parental deprivation or neglect (Kolb et al., 2012).

FURTHER REFLECTION: *Imagine that you are advising parents of infants about how to promote their child's cognitive development. What caregiving practices are most likely to foster an infant's ability to develop a sense of causality? What caregiving practices are most likely to help infants understand and categorize objects?*

Communication

OBJECTIVE 4 Summarize the beginnings of language competence from birth through the first 2 years of life.

After birth, infants see and hear people talking, making gestures, and combining language with actions. So even though infants may not be active partners in the spoken language of their home and culture from birth, they do participate in rhythmic communication exchanges through gazing, smiling, cooing, and coordinated play. Research on language development has focused on the many forerunners of language competence that emerge from birth through the first 2 years of life (Parish-Morris, Golinkoff & Hirsh-Pasek, 2013).

Thought and language travel independent courses that typically intersect during the second year of life. Before that time, babies exhibit meaningful communication that does not require speech, such as pointing and gesturing and vocalizations that are not meaningful, such as babbling and cooing. A rare genetic disease, Williams syndrome, illustrates that the capacities for language and cognition are distinct. Children with Williams syndrome are typically very talkative and sociable; they develop a large vocabulary and speak in grammatically correct sentences. Although their speech indicates some developmental abnormalities, it is much further advanced than their other cognitive functions. For example, children with Williams syndrome may have difficulty with tasks that are easy for most middle-school-age children, like tying their shoes, subtracting 2 from 4, or writing their street address (Schultz, Grelotti, & Pober, 2001). This genetic condition forces one to think about language competence separate from other cognitive abilities. Of course, one does not have to go to the extreme of people with Williams syndrome to find examples of people whose speech seems disconnected from their ability to think and reason.

Language Perception

Infants are able to recognize sounds and differentiate between sound combinations long before they are able to produce language or understand word meaning. This capacity to recognize language sounds, including the combinations of sounds made by letters and words and the rise and fall of pitch as words and sentences are spoken, is called **language perception** (Tsao, Liu, & Kuhl, 2004). Young infants are able to hear and distinguish among the major language sounds used in natural language. By 5 months of age, infants are able to recognize the difference between words that emphasize the first syllable, like *father*, and words that emphasize the second syllable, like *begin*. By this age, they also recognize the sound of their own name (Mandel, Jusczyk, & Pisoni, 1995; Weber, Hahne, Friedrich, & Friederici, 2004). Over the first year of life, there is a universal process of narrowing, in which infants become less sensitive to the sound distinctions that are not present in the spoken language of their family. This mechanism contributes to language acquisition by attuning the infant's ear to the important and possibly subtle distinctions of their native language (Plamer, Fais, Golinkoff, & Werker, 2012).

Babbling

Babbling, initially characterized by sounds used in many languages, begins to reflect the sounds and intonation infants are most likely to hear. By about 6 months of age, sounds they do not hear dropout of their babbling and, at about this same time, they become less able to tell the differences among sounds not found in their native language (Hoff, 2013). This environmental shaping of language competence provides another example of the plasticity of brain functions. Some networks grow and become strengthened by experience, whereas others wither.

At around 6 to 10 months, babbling begins to take on a special character, connecting consonants and vowels and repeating these combinations. Although parents may eagerly receive this type of babbling as evidence of first words (i.e., *baba*, *mama*, *dada*), there is debate about whether these repetitions of babbling sounds have a symbolic value.

One sound that is especially important in the parenting process is "Mama." The infant word for mother has many similarities across hundreds of language groups. In a study of "Mama" sounds, a pediatrician asked 75 parents of newborns in his practice to listen for *mama* sounds (Goldman, 2001). If they heard one, he asked them to note the infant's age; the circumstances of the sound (time of day, etc.); if they could determine whether the infant wanted something, and if so, what; and if the sound was directed at anyone, to whom it was directed. Of the 75 parents, 52 spoke only English. Other languages included Spanish, Hindi, Italian, Russian, Hebrew, Ibo, Chinese, and some combinations of Spanish and Greek or Italian. Fifty-five of the parents heard a *mama* sound, often as part of a cry. Thirty-two infants made the *mama* sound for the first time in the first 2 months of life. It became more distinct and more of a whine or call as it was repeated over the first 6 months. For those babies who made *mama* sounds, the sound was interpreted as an indication of wanting—especially wanting to be picked up, wanting attention, or wanting to be taken out of the crib or infant seat and entertained. An implication of this research is that by 2 months, many infants have the ability to use a non-crying vocalization to serve as a call that brings caregiver attention.

Studies using brain scans of infants as they listened to nonsense syllables found that very young infants, only 2 and 3 days old, were more responsive to words with repeated syllables (e.g. penana) than to word sounds that did not have repeated syllables (e.g. penaku). Brain activity increased when the words with repeated sounds were played. The implication is that infants across cultures are ready to attend to these kinds of word sounds and find them interesting, giving words like "mama" and "dada" a favored position in the ocean of language sounds in which they are immersed (Live Science Staff, 2011).

Communication with Gestures

By 8 months, infants use sounds like grunting and whining in combination with **gestures** to achieve a goal. Sounds combined with gestures and looks in a certain direction become part of purposeful **communication**—trying to get the caregiver to reach a cookie or get a certain toy off the shelf. A common first gesture is to raise the arms up toward the caregiver in a desire to be picked up. Gestures may also be used to express emotion or to get someone's attention. When Jakob was about 14 months, he used the gesture of shaking his hands to signal that he was all done with his food. This was much preferred to having him throw the food on the floor!

Three other communicative strategies emerge at about 9 to 11 months. Infants begin to seek adult interest and attention by *showing* them objects and thereby initiating an interaction. Soon after showing, the infant begins *giving* objects. Adults who are willing to engage in this type of exchange will find the baby bringing them a whole variety of toys, utensils, and pieces of dirt or dust for inspection. Following giving, a common next key gesture is *pointing*. There is some debate about whether pointing is a form of reaching or a way of getting an adult's attention to notice an object. In either case, it is an example of an infant's ability to set up a shared focus with another person on the same object, thereby creating a common point of reference. This is called **intersubjectivity**—a condition in which two conscious minds have the same thought or feeling. The role of gestures in establishing intersubjectivity is an excellent example of the interdependence of motor, social, and psychological systems as they combine to support language development (Gallagher, 2013).

Gestures are a way for a nonverbal child to ask for additional information. Pointing or reaching may be precursors of asking a question like "What is this?" or "Where is this?" This preverbal question-asking behavior is fundamental to the knowledge acquisition process and illustrates the child's early active role in seeking information (Chouinard, 2007). Gestures can also be a child's way to get additional reassurance, or to communicate needs and interests. The way that adults respond to these gestures, by ignoring them, responding to them, or providing additional information once the initial request or question has been addressed, illustrates

Kissing, nose rubbing, and hugging are early gestures that communicate affection between mother and baby.

the parents' active role in establishing a child's confidence that communications will be recognized and reciprocated.

Baby Signs. Building on the emerging capacity of infants to invent gestures for shared communication, Linda Acredolo and Susan Goodwyn began to study the role of symbolic gestures in preverbal infants. During the second year of life, it is not uncommon for infants and their caregivers to use symbolic gestures, like waving bye-bye, putting the thumb to the mouth to request or refer to a bottle, or using a throwing motion to suggest playing ball. Infants are avid observers of such action-meaning combinations, and once established, parents seem enthusiastic about using them to enhance communication. Following these naturalistic observations of symbolic gestures, Acredolo and Goodwyn conducted experimental research to increase parents' use of symbolic gestures with their infants and to evaluate the impact of this intervention on subsequent language development. One question their research addressed was whether exposure to an expanded capacity for symbolic gestures might replace a child's need for spoken language and thereby delay language production.

In one study, healthy, 11-month-old babies were taught gestures for five objects and three nonobject concepts: "fish" [SMACKING LIPS], "flower" [SNIFFING], "bird" [FLAPPING ARMS], "airplane" [SWOOPING HAND MOVEMENT], "frog" [FIST OPEN AND CLOSE], "Where is it?" [PALMS UP AND OUT], "more" [FINGER TO OPPOSITE PALM], and "all gone" [PALM DOWN, BACK AND FORTH]. Families were encouraged to invent their own additional gestures and were also given toys to take home that corresponded to the target words in order to encourage the use of gestures. Follow-up telephone interviews were conducted every 2 weeks to learn about how often and in what contexts the gesturing was taking place. Infants were tested at 11 months to establish their initial level of use for gestures or words. They were tested again at 15, 19, 24, 30, and 36 months to evaluate both expressive and receptive language. This group was compared to two other groups of infants who did not receive training in early gestures (Goodwyn, Acredolo, & Brown, 2000).

In the follow-up phone conversations it was determined that the infants had acquired an average of 20 gestures that were initiated by the infant and were used regularly. Babies showed advanced performance in expressive and receptive language as well as advances in their ability to use two-word combinations at 15, 19, and 24 months. There were no significant differences between the symbolic gesture group and the control group at 36 months.

The value of early signing for hearing infants may not be its advantage for eventual long-term language competence, but for its contribution to a caregiver's increased understanding of an infant's needs. Parents who recognize an infant's sign for "all done," "more" or "water" can respond more readily and appropriately to the infant's needs (Acredolo, Goodwyn, & Abrams, 2009). Needless to say, the use of signs and gestures plays an intricate role in communication with deaf infants as part of a rich, multidimensional approach to pre-symbolic language acquisition (Günther & Hennies, 2012).

Early Grammar Recognition

Grammar refers to rules that guide the combination of words and phrases in order to preserve meaning. In English, for example, sentences are usually formed from nouns (people, places, or things) or noun phrases, followed by verbs (actions) or verb phrases (e.g., "The girl reads the book"). Certain cues about the way words are used in a sentence or their order in a sentence convey their meaning. For example, the word "the" is a signal that a noun will follow.

By 7 to 8 months of age, infants show the ability to recognize the specific regularities in spoken speech and to detect rules about the combination of language sounds. For example, babies were habituated to 2 minutes of a grammar in which sentences followed an ABA form, such as *ga ti ga*, or a grammar that followed the ABB form, such as *ga ti ti*. In the test situation, babies recognized the difference between the grammar to which they were habituated and an inconsistent grammar made up of entirely different sounds (Marcus, 2000). The implication of these findings is that long before babies can produce words, word phrases, or grammatically correct sentences, they are gathering information about the rules that hold sounds and phrases together in order to make meaning (Rabagliati, Senghas, Johnson, & Marcus, 2012).

First Words

Between 12 and 18 months of age **words** emerge as more salient than gestures as a way to refer to objects (Namy & Waxman, 2002). Around the age of 8 months, infants understand the meanings of some individual words and phrases. This ability to understand words, called **receptive language**, precedes **language production**, the ability to produce spoken words and phrases. You can direct a baby's glance by saying, "Look at the flowers," or "Do you want candy?" At this age, babies can go through their paces in the ever delightful game of "point to your nose, eyes, ears," and so on. The number of words infants understand increases rapidly after 12 months. According to one analysis, 16-month-olds have a receptive vocabulary of between 92 and 321 words (Fenson et al., 1994).

One of the first significant events in the development of language production is the *naming* of objects. With repetition, a sound or word becomes associated with a specific object or a set of related objects. For example, a child may say *ba* whenever she sees her bottle. If she is thirsty and wants her bottle, she may try saying *ba* in order to influence her caregiver to produce the bottle. Gestures, actions, and facial expressions often accompany the baby's word, which help establish its meaning in the caregiver's mind. If the baby's word has meaning to the caregiver and serves to satisfy the baby's needs, it will probably be retained as a sign. The word *ba* may come to mean "bottle" and other liquids such as juice, water, or milk.

The important characteristic of **first words** is their shared meaning. Even though *ba* is not a real word, it functions in the same way that any noun does—it names a person, place, or thing. These single-word utterances accompanied by gestures, actions, vocal intonation, and emotion are called **holophrases**. They convey the meaning of an entire sentence. For example, saying "ba, ba" in a pleading tone while pointing to the refrigerator and bouncing up and down conveys the meaning "I need a bottle," or "Get me the bottle." Gradually, the child discovers that every object, action, and relationship has a name. Rapid progress occurs between 12 and 16 months in the naming of objects. By 16 months a typical infant has a productive vocabulary of 26 words. Table 5.5 provides a summary of milestones in language over the first 18 months of life.

Young children first talk about what they know and what they are interested in. Common first words include important people (*Mama, Dada*, names of siblings), foods, pets, toys, body parts (*eye, nose*), clothes (*shoe, sock*), vehicles (*car*), favorite objects (*bottle, blanket, phone*), other objects in the environment (*keys, trees*), actions (*up, bye-bye, yes, no, please, down, more*), pronouns (*you, me*), and states (*hot, hungry*). One hypothesis is that first words are those that are rich with imagery. Whether words are nouns or verbs is not as important as whether an infant has been able to form a mental representation of what the word refers to (McDonough, Song, Hirsha-Pasek, Golinkoff, & Lannon, 2011). Lois Bloom (2004) has suggested that a "principle of relevance" guides the early acquisition of new words. Babies pay special attention to words and expressions that are most closely linked with what they are doing and thinking about at the time. For that reason, the actual vocabulary that is acquired during infancy is quite idiosyncratic, reflecting the themes and experiences of each child's everyday life (Polka, Rvatchew, & Mattock, 2009).

FURTHER REFLECTION *Analyze the role of gestures in early communication. What is the importance of gestures? How do they contribute to the establishment of intersubjectivity? How much and in what contexts do you continue to rely on gestures to convey meaning?*

Attachment

OBJECTIVE 5 Analyze social attachment, the process through which infants develop strong emotional bonds with others, and describe the dynamics of attachment formation during infancy.

Have you ever wondered how feelings of love and connectedness form between babies and their caregivers? At birth, an infant has some familiarity with the sound and rhythm of the mother's voice, but a newborn does not show evidence of a specific emotional preference for the biological mother over other responsive adults. By the end of the first year of life, however, babies not only know their caregivers but also have very strong emotional preferences for these adults over all others. **Attachment** is the process through which people develop specific, positive emotional bonds with others. John Bowlby proposed the notion

Table 5.5 Early Communication Milestones

By the End of 3 Months	By the End of 6 Months	By the End of 12 Months	By the End of 18 Months
Smile when you appear. Startle upon hearing loud sounds. Make cooing sounds. Quiet or smile when spoken to. Seem to recognize your voice. Cry differently for different needs.	Make gurgling sounds when playing with you or left alone. Babble repetitive syllables such as ba, ba or ma, ma. Use voice to express pleasure and displeasure. Move eyes in the direction of sounds. Respond to changes in the tone of your voice. Notice that some toys make sounds. Pay attention to music.	Try to imitate words. Say a few words, such as dada, mama, and oh, oh. Understands about 50 words and simple instructions, such as "please drink your milk." Understands "no." Turn and look in the direction of sounds.	Point to an object or picture when it is named. Recognize names of familiar people, objects, and body parts. Follow simple directions accompanied by gestures. Say as few as 8 to 10 and as many as 180 words (great degree of normal variability in spoken vocabulary at this age).

This table is adapted from information on the Mayo Clinic website, Language Development: Speech Milestones for Babies, www.mayoclinic.com/health/infant-development/AN01026

Art Media/Heritage-Images/The Image Works

Close physical contact during nursing provides infants with a combination of sensory stimuli—sight, sound, smell, and touch—that contribute to the formation of an early scheme for their mother.

of the **attachment behavior system** as an organized pattern of infant signals and adult responses that lead to a protective, trusting relationship during the very earliest stage of development. The nurturing responses of the caregiver form a corresponding behavioral system referred to as **parenting** or **caregiving** (Ainsworth, 1985; Bowlby, 1988).

From ethological and neurobiological perspectives, the coordinated attachment and caregiving systems form a pattern of mutual regulation through which the infant alerts the caregiver to distress, and the caregiver provides protection, comfort, and care. Given the prolonged dependent status of human infants, this attachment/caregiving system is a foundation of survival. Through repeated sensory, motor, and communication experiences, it creates the embodiment of a social-emotional relational context that is forged and reinforced in the establishment of neural pathways, interconnections, and biochemical processes. These biological and neural responses are associated with threat reduction, comfort or discomfort, and sensitive or insensitive care. Infants' experiences, especially under conditions of threat or distress, set the stage for their own ability to regulate their emotions and to establish significant relationships over the next stages of life (Schore, 2013).

The Development of Attachment

Attachment theorists have described a sequence of stages in the formation of the attachment relationship (Ainsworth, 1973, 1985; Bowlby, 1969/1982, 1988; Marvin & Britner, 2009) (see Table 5.6). Many of the sensory and motor competencies described earlier in this chapter contribute to an infant's ability to establish a vivid mental representation of the primary caregiver and to stimulate caregiving behaviors. During the first 3 months of life, infants engage in a variety of behaviors, including sucking, rooting, grasping, smiling, gazing, cuddling, crying, and visual tracking or following, which serve to maintain closeness with a caregiver or bring the caregiver to the infant. Through these contacts, babies learn about the unique features of their caregivers. Caregivers, for their part, use a variety of strategies including eye contact, touching and holding, and vocalizing as means of establishing and maintaining social engagement with their infants (Akhtar & Gernsbacher, 2008). Caregivers and infants experience repeated interactions that result in the formation of predictable patterns. Rhythmic patterns of interaction lay the foundation for expectations about communication.

From about 3 to 6 months, an infant's attachment is expressed through preferential responsiveness to a few familiar figures. Infants smile more at the familiar person than at a stranger. They show more excitement at that person's arrival and appear to be upset when that person leaves. During this phase, babies initiate more interactions toward the familiar caregiver. They are able to control the interaction by linking a chain of behaviors into a more complex sequence. In Stage 1, for example, the baby may look intently at the primary caregiver. In Stage 2, the baby looks intently, reaches toward the caregiver's face, and pulls the caregiver's hair.

Table 5.6 Five Stages in the Development of Attachment

Stage	Age	Characteristics
1	Birth to 3 months	Infant uses sucking, rooting, grasping, smiling, gazing, cuddling, crying, and visual tracking to maintain closeness with caregivers.
2	3 to 6 months	Infant is more responsive to familiar figures than to strangers.
3	6 to 9 months	Infant seeks physical proximity and contact with objects of attachment.
4	9 to 12 months	Infant forms internal mental representation of object of attachment, including expectations about the caregiver's typical responses to signals of distress.
5	12 months and older	Child uses a variety of behaviors to influence the behavior of the objects of attachment in ways that will satisfy needs for safety and closeness.

With Dad nearby, Jakob can begin to explore this new environment and return to his secure base as needed.

From about 6 to 9 months, babies want to be physically close to the object(s) of attachment. The ability to crawl and to coordinate reaching and grasping contribute to greater control over the outcomes of their actions. In this phase, babies experiment with finding an optimal distance from the caregiver. They may crawl away, look back, and then, depending on the caregiver's perceived availability, crawl back to the caregiver or smile and continue exploring. If the caregiver is preoccupied or out of sight, the baby may cry to bring the caregiver closer or to reestablish contact.

From about 9 to 12 months, babies form mental representations of their caregivers. This mental picture provides the first robust **working model of an attachment** relationship. Specific characteristics of a caregiver and expectations about how the caregiver will respond to the infant's actions are organized into a complex attachment scheme that includes expectations about how the caregiver will respond when the child is frightened, hurt, or distressed.

In toddlerhood and later, young children use a variety of behaviors to influence the behavior of their parents and other objects of attachment in order to satisfy their own needs for closeness. Bowlby described this new and important capacity as the creation of a **goal-corrected partnership**. Children may ask to be read to, cuddled at bedtime, and taken along on errands. These and other strategies produce caregiver behaviors that will satisfy a child's continuing needs for physical contact, reassurance, closeness, and love.

As children get older, they begin to think about new risks and threats to their security. They may initiate new strategies for maintaining closeness to the objects of their attachment. Especially when they are experiencing unusual stress, as in times of illness, divorce, or rejection, children of any age may try to activate the attachment system by sending signals that are intended to evoke the caregiver's comfort and closeness.

Stranger Anxiety

During the second half of the first year, two signs of a child's growing attachment to a specific person are observed: stranger anxiety and separation anxiety. **Stranger anxiety** refers to the baby's discomfort or tension in the presence of unfamiliar adults. By 6 months of age, most babies can distinguish a picture of their mother from a picture of a stranger (Swingler, Sweet, & Carver, 2010). Babies vary in how they express their protest to strangers and in how intensely they react (Rieser-Danner, 2003). They may cling to their parents, refuse to be held, stiffen at the stranger's touch, or merely avert their eyes from the stranger's face.

The baby's response to a stranger depends on specific features of the situation, including how close the caregiver is, how the stranger approaches the baby, and how the caregiver responds to the stranger. For example, if a mother speaks in a positive tone of voice to her baby about a stranger, the baby's response to the stranger is likely to be positive. In contrast, if the mother interacts with the stranger in a socially anxious manner, the baby will be more fearful of the stranger. This effect is especially notable in infants who are temperamentally more fearful and inhibited (deRosnay, Cooper, Tsigaras, & Murray, 2006).

The baby's response to a stranger will also be influenced by the amount of prior experience with unfamiliar adults. Strangers are more unfamiliar to infants in some cultures and contexts than in others (Rothbaum, Morelli & Rusk, 2011). In some parts of the world, babies rarely come into contact with anyone outside of their small village. In contrast, some children are in child care arrangements where adults frequently come and go. Normally, wariness of strangers is considered a positive developmental sign—that is, babies are able to detect the differences between their parents and adults they do not know. Wariness of strangers continues to be expressed throughout life. In fact, one often sees stronger expressions of suspiciousness or fear among adults encountering strangers than among babies.

Separation Anxiety

At about 9 months, infants give another indication of the intensity of their attachment to their parents. They express rage and despair when their parents leave them. This reaction is called **separation anxiety**. Just as with stranger anxiety, a baby's response to separation depends on the conditions. Infants are less distressed when their primary caregiver leaves them alone in a room at home than when they do so in a laboratory. They are less likely to protest if the caregiver leaves the door to the room open than if she closes the door as she leaves. Separation from the mother for periods of 30 minutes has been identified as a distinct source of stress for babies 9 months of age and older. Neurological and biochemical evidence of stress, including increases in adrenocortical activity and concentrations of cortisol in the saliva, were associated with 30 minutes of separation from the mother in a laboratory situation. The impact of stressful separations can be seen in the disruption of basic physical patterns, especially sleep disturbances, and in regression to more immature forms of play behavior, aimless wandering, and altered interactions with peers and teachers in the child care setting (Coan, 2016).

A baby's responses to separation and reunion have been used as key behavioral indicators of attachment quality. Babies who are described as having an insecure attachment are more distressed when they are separated from their mothers, and the mothers appear to be less responsive in calming their babies following separation (Harel & Scher, 2003).

Over time, most babies become more flexible in response to parents' temporary departures. Young children learn to tolerate brief separations. By the age of 3, children may even look forward to a night with a babysitter or an afternoon at grandfather's house. Once the attachment is fully established, many children can comfort themselves by creating mental images of their parents and by remembering their parents' love for them. During infancy, however, the parents' physical presence remains a focal point of attention and concern.

Formation of Attachments with Mother, Father, and Others

Most infants have more than one caring person with whom they form an attachment. Most commonly, the first object of attachment is the mother, but fathers, older siblings, grandparents, and child care professionals also become objects of attachment. Several factors have been identified as important for predicting which people will form the infant's hierarchy or radius of significant attachment figures (Cassidy, 2016; Howes & Spieker, 2016):

1. The amount of time the infant spends in the care of the person.
2. The quality and responsiveness of the care provided by the person.
3. The person's emotional investment in the infant.
4. The presence of the person in the infant's life across time.

Patterns of Attachment

It is important to distinguish between the presence of an attachment and the quality of that attachment. According to attachment theory, if an adult is present to interact with the infant, an attachment will be formed. However, individual differences emerge in the quality of that attachment depending on the accumulation of information the infant gathers over many instances when the infant is seeking reassurance, comfort, or protection from threat (Weinfield, Sroufe, Egeland, & Carlson, 2008). The adults' acceptance of the infant and their ability to respond to the child's varying communications are important to forming a positive, secure attachment. The caregivers' patterns of expressing affection and rejection will influence how well babies can meet their strong needs for reassurance and comfort.

The Strange Situation. Early research on individual differences in the quality of attachment was carried out through systematic observations of babies and their caregivers in a standard laboratory procedure called the strange situation (Ainsworth, Blehar, Waters, & Wall, 1978; Bretherton, 1990). Much of this research involved babies with their mothers. As a consequence, results are typically reported in regard to the attachment styles of infants and their mothers. During an approximately 20-minute period, the child is exposed to a sequence of events that are likely to stimulate the attachment behavior system (see Table 5.7). The situation introduces several potentially threatening experiences, including the presence of a stranger, the departure of the mother,

Table 5.7 The Strange Situation Laboratory Procedure

Episode	Duration	Participants*	Events
1	30 seconds	M, B, O	O shows M and B into the room, instructs M on where to put B down and where to sit; O leaves.
2	3 minutes	M, B	M puts B down close to her chair, at a distance from the toys. She responds to B's social bids but does not initiate interaction. B is free to explore. If B does not move after 2 minutes, M may take B to the toy area.
3	3 minutes	M, B, S	This episode has three parts. S enters, greets M and B, and sits down opposite M without talking for 1 minute. During the second minute, S engages M in conversation. S then joins B on the floor, attempting to engage B in play for 1 minute. At the end of this episode, M leaves "unobtrusively" (B usually notices).
4	3 minutes	B, S	S sits on her chair. She responds to B's social bids but does not initiate social interaction. If B becomes distressed, S attempts to comfort B. If this is not effective, M returns before 3 minutes are up.
5	3 minutes	M, B	M calls B's name outside the door and enters (S leaves unobtrusively). If B is distressed, M comforts B and tries to reengage B in play. If B is not distressed, M goes to sit on her chair, taking a responsive, noninitiating role. At the end of the episode, M leaves, saying, "Bye-bye; I'll be back."
6	3 minutes	B	B remains alone. If B becomes distressed, the episode is curtailed and S enters.
7	3 minutes	B, S	S enters, comforting B if required. If she cannot comfort B, the episode is curtailed. If B calms down or is not distressed, S sits on her chair, taking a responsive role as before.
8	3 minutes	M, B	M returns (S leaves unobtrusively). M behaves as in episode 5.

*O = observer; M = mother; B = baby; S = stranger.

Source: Data from "Open Communication and Internal Working Models: Their Roles in the Development of Attachment Relationships," by I. Bretherton, in R. Dienstbier and R. A. Thompson (eds.), *Nebraska Symposium on Motivation, 1988: Socioemotional Development*, 36, pp. 60–61.

being left alone with a stranger, and being left completely alone—all in the context of an unfamiliar laboratory setting. During this sequence, researchers have the opportunity to make systematic observations of the child's behaviors, the caregiver's behaviors, and the characteristics of their interactions. Four infant behaviors were of special importance: contact maintenance, proximity seeking, avoidance, and resistance. These behaviors were coded and compared across varying segments of the procedure.

Four Patterns of Attachment. Using the strange situation method, four patterns of attachment behavior have been identified: (1) secure attachment, (2) avoidant attachment, (3) resistant attachment, and (4) disorganized attachment.

Infants who have a **secure attachment** actively explore the laboratory setting and interact with strangers while their mothers are present. After separation, the babies actively greet their mothers or seek interaction. If the babies were distressed during separation, once the mothers return the infants go to the mothers for comfort, and the mothers effectively reduce their distress. Then the babies resume exploring the environment.

When observed at home, babies who have a secure attachment cry less than other babies (Ainsworth, 1985; Tracy & Ainsworth, 1981). They greet their mothers more positively on reunion after everyday separations and respond more cooperatively to their mothers' requests. One can sense that securely attached babies have a working model of attachment in which they expect their caregiver to be accessible and responsive. Mothers of infants who have secure attachments are able to talk openly and coherently about their own childhood attachment figures and attachment behaviors (van Ijzendoorn, 1995).

Infants who show an **avoidant attachment** avoid contact with their mothers during the reunion segment following separation or ignore their efforts to interact. They appear to expect that their mothers will not be there when needed. They show less distress at being alone than other babies. Mothers of babies who were characterized as avoidant seem to reject their babies. It is almost as if they were angry at their babies. They spend less time holding and cuddling their babies than other mothers, and more of their interactions are unpleasant or even hurtful. At home, these babies cry a lot, they are not readily soothed by contact with the caregiver, and yet they are quite distressed by separations. Mothers of infants who show an avoidant attachment are often dismissive or devaluing of their own childhood attachment experiences (Main & Solomon, 1990).

Infants who show a **resistant attachment** are very cautious in the presence of the stranger. Their exploratory behavior is noticeably disrupted by the caregiver's departure. When the caregiver returns, the infants appear to want to be close to the caregiver, but they are also angry so they are very hard to soothe or comfort. Infants who are characterized as resistant have mothers who are inconsistent in their responsiveness. Sometimes, these mothers ignore clear signals of distress. At other times, they interfere with their infants in order to make contact. These infants do not know if their needs will be attended to. Although these mothers enjoy close physical contact with their babies, they do not necessarily do so in ways appropriate to the baby's needs. The result is the formation of an internal working model of attachment that is highly unpredictable. These babies try to maintain proximity and avoid unfamiliar situations that increase uncertainty about accessibility to their caregiver. Caregivers of infants who have formed a resistant attachment are overly preoccupied with conflicts around their own childhood attachment issues.

In the **disorganized attachment**, babies' responses are particularly notable in the reunion sequence. These babies have no consistent strategy for managing their distress. They behave in contradictory, unpredictable ways that seem to convey feelings of extreme fear or utter confusion (Belsky, Campbell, Cohn, & Moore, 1996). Observations of mothers and infants who are described as having a disorganized attachment highlight two different patterns. Some mothers are negative, intrusive, and frighten their babies in bursts of intense hostility. Other mothers are passive and helpless, rarely showing positive or comforting behaviors. These mothers appear to be afraid of their babies, perhaps not trusting their own impulses to respond appropriately (Lyons-Ruth, Lyubchik, Wolfe, & Bronfman, 2002). The mothers often have experiences of loss or abuse in their childhood that have disrupted their own attachment experiences. Only a small percentage of infants show the disorganized pattern. Research has suggested links between the disorganized attachment and serious mental health problems in later childhood and beyond, including depression, borderline personality, and dissociative reactions (Fonagy, 2003; Lyons-Ruth et al., 2002; Lyons-Ruth & Jacobvitz, 2016).

Although categories of attachment style are still widely used in the developmental literature, the idea of attachment types or categories has come under some criticism (Waters & Beauchaine, 2003). The strange situation and its related script and coding system may constrain features of the attachment system, resulting in the emergence of a typology. In real-life situations, the expression of attachment behaviors is likely to be more fluid, adapted to the changing nature of the caregiver's responses and the conditions that provoke infant distress. Some authors prefer to think of attachment as characterized by underlying dimensions. For example, Fraley and Spieker (2003) suggested that individual differences in infant attachment can be captured along two dimensions: (1) proximity seeking versus avoidance and (2) anger and resistance. Children who are high on proximity seeking and low on anger might be thought of as secure. Children who are high on proximity seeking and high on anger might be thought of as resistant. But the exact nature of a child's working model of attachment may be more accurately characterized as some combination of these dimensions.

Parental Sensitivity and the Quality of Attachment

How can we account for differences in the quality of attachment? A cornerstone in the formation of a secure attachment is caregiver sensitivity. **Sensitivity** is defined as attentiveness to the infant's state, accurate interpretation of the infant's signals, and well-timed responses that promote mutually rewarding interactions (Mesman, Oster, & Camras, 2012). A sensitive caregiver is able to recognize the infant's emotional state, empathize with it, and make an appropriate response. An insensitive parent might recognize that the infant is distressed but be too busy or preoccupied to respond and provide effective comfort.

Caregivers who are psychologically available, responsive, consistent, and warm in their interactions with their babies—especially during the first 6 months of the baby's life—are found to be most successful in establishing a secure attachment relationship that can be measured by the time the baby is 12 months old (Braungart-Rieker, Garwood, Powers, & Wang, 2001). The way caregivers respond when infants are distressed is uniquely related to the formation of a secure attachment independent of how they respond to other infant cues (Leerkes, Blankson, & O'Brien, 2009). This makes sense since the attachment system is theorized to be especially adapted to protecting infants from threat. The **Applying Theory and Research to Life** box discusses the possibility that there may be a sensitive period for the development of attachment.

APPLYING THEORY AND RESEARCH TO LIFE

Is There a Sensitive Period for Attachment?

A **sensitive period** is a time of utmost readiness for the development of certain skills or behavior patterns. The particular skill or behavior pattern is not likely to emerge before the onset of the period, and it is extremely difficult if not impossible to establish once the sensitive time period has passed. The successful emergence of any behavior that has a sensitive period for development depends on the coordination of the biological readiness of the organism and environmental supports (Scott, 1987).

Konrad Lorenz (1935, 1937/1961) described a process of social attachment among birds that he called imprinting. In this process, the young bird establishes a comparatively permanent bond with its mother. In her absence, however, the young bird will imprint on other available targets, including a model of its mother or a human being. For birds, the onset of this sensitive period coincides with the time at which they are able to walk and ends when they begin to fear strangers. After this point, no new model or species can be substituted as a target for imprinting.

Is there a time when infants are most likely to form such an attachment to their primary caregiver? Is there a point after which such attachments cannot be formed? The answer to these questions is especially relevant for policies related to foster care and adoption. We need to know about the plasticity of social attachment in order to support optimal social and emotional development.

Evidence to address these questions has been drawn from real-life situations in which mother–infant relationships have been disrupted. Leon Yarrow (1963, 1964, 1970) observed 100 infants who were shifted from foster mothers to adoptive mothers. The infants who were separated from their foster mothers at 6 months or earlier showed minimal distress. They did not express prolonged anger or depression over the separation if their physical and emotional needs continued to be met. In contrast, all the infants who were transferred from foster mothers to adoptive mothers at 8 months or older showed strong negative reactions, including angry protest and withdrawal. These infants found the disruption of their earlier relationships very stressful.

Later research by John Bowlby (1980) focused on adolescents who had moved repeatedly from one foster home or institution to another. These children never had an opportunity to form an enduring, loving relationship with a caring adult. As adolescents, they were described as affectionless and unable to form close relationships with others. Subsequent studies of adopted children have confirmed that children who spend their infancy in institutions where the turnover in caregivers is high show disruptions in social functioning, including indiscriminate friendship formation, difficulty in forming close relationships, and difficulty in finding emotional support from peers (Rutter, 2012).

In the 1990s, a large number of orphans from Romania were adopted by families in the United States, Canada, and several European countries. While they were in the Romanian orphanages, these children had been exposed to a variety of neglectful conditions including poor nutrition, little attention or adult interaction, and long periods of time in their cribs with little opportunity for stimulation or play. Those who were

Nina Leen/Time & Life Pictures/Getty Images

Konrad Lorenz inadvertently became the target of imprinting for these geese. They followed him as if he were their mother.

adopted by 4 months of age seemed to develop quite normally. However those who were adopted at 8 months of age or older had a wide range of cognitive and affective problems that lasted into childhood. In particular, those who had longer exposure to the Romanian orphanages had disrupted social competence characterized by an overly friendly style of interaction, regardless of whether the person was a familiar caregiver or a complete stranger, and a lack of close connection to their adoptive parents (Carlson & Earls, 1997; Gunnar, 2000; Rutter et al., 2010).

In a study of children who spent their first years of life in an institution where the quality of care was good but staff turnover was high, children who were adopted at age 2 were able to form secure attachments to their adoptive parents. However, at later observations at ages 8 and 16, the children showed evidence of difficulty in peer relations similar to the children who remained in the institution (Hodges & Tizard, 1989).

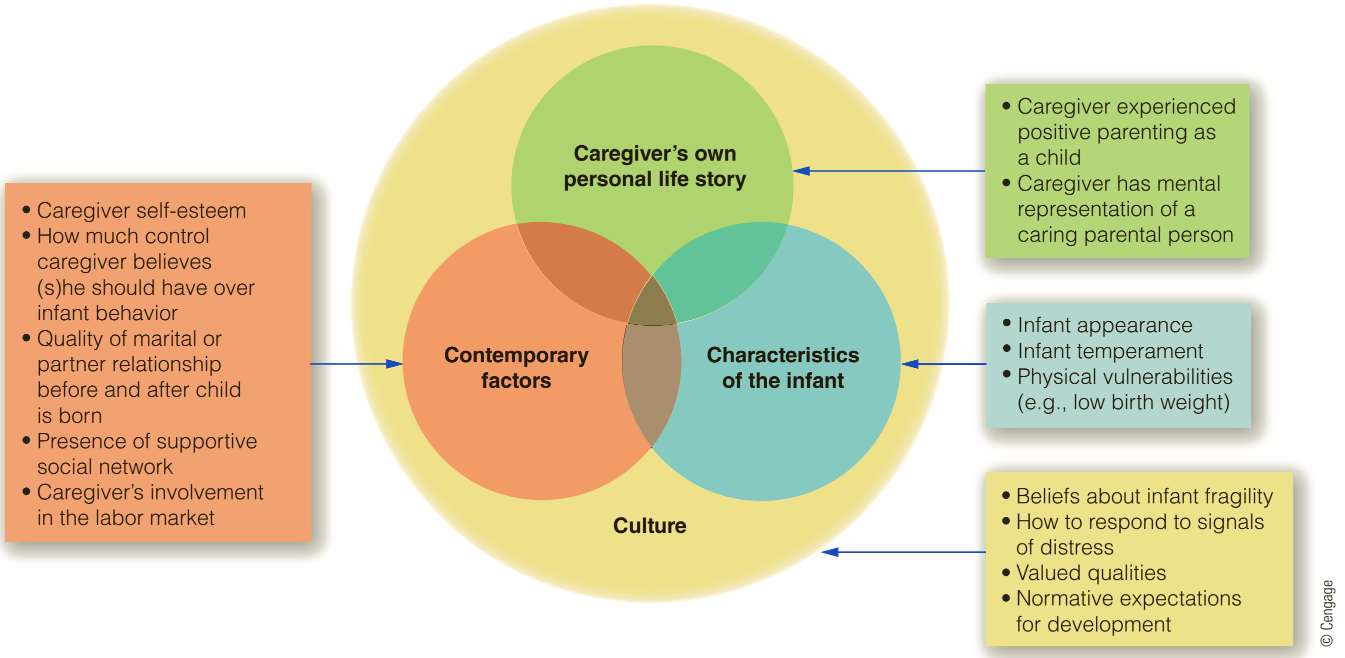
From these real-world examples of inconsistent or disrupted caregiving relationships, we can say that a sensitive period for attachment must begin at about 6 months of age. Whereas lack of continuity in caregiving during infancy is likely to produce long-lasting disruptions in relationship formation, it is not clear if there is a time after which a secure attachment can no longer be established.

Critical Thinking Questions

1. Design a research study to evaluate whether there is a sensitive period for the formation of a secure attachment. What kinds of evidence would be needed to determine whether there is a sensitive period for attachment?
2. In your research plan, explain how you could determine whether the problems arising from disruptions in early caregiving were a result of a lack of attachment or some other explanation such as poor nutrition or lack of stimulation.
3. Identify other aspects of infant development that might be characterized as having a sensitive period.
4. Apply what you have read about attachment to policies that guide practices related to foster care and adoption.

Four factors come into play in producing the kind of sensitivity that underlies secure attachments: (1) cultural and subcultural pathways, (2) the caregiver's personal life story, (3) contemporary factors, and (4) characteristics of the infant (see FIGURE 5.4 ▶).

Cultural and Subcultural Pathways. Cultural and subcultural pathways are integrated into one's mental representation of a parent or caregiver. The culture's beliefs about infants, including how fragile or vulnerable they are, how best to help infants cope with distress, and what skills or temperamental qualities are most valued, are likely to shape a caregiver's practices (Coll, 2004). For example, Japanese mothers keep close, continuous proximity to their infants. Separations are infrequent, and infants are expected to monitor their mothers' reactions in order to assess people and objects in the environment. Japanese mothers subtly direct their infants' play behavior through gestures and facial expressions. Independent play is not especially valued, and the



• Caregiver self-esteem
• How much control caregiver believes (s)he should have over infant behavior
• Quality of marital or partner relationship before and after child is born
• Presence of supportive social network
• Caregiver's involvement in the labor market

FIGURE 5.4 ▶ FACTORS CONTRIBUTING TO CAREGIVER SENSITIVITY idea that children would handle separation and reunion with the mother with little distress is not expected by Japanese caregivers (Okimoto, 2001).

In-depth observations of behaviors central to the survival of a group, such as caregiving strategies, establish that many cultures practice shared child care. When many adults and older siblings share responsibility for infant care, a child's needs can readily be met. When mothers expect to be able to share the tasks of infant care with others, they may also have a different ideal about the quality of infant attachment, a model that is less exclusive and possibly less emotionally intense. As a result, infants emerge with a more confident mental representation about the willingness of others to protect and care for them (Seymour, 2004).

The Caregiver's Personal Life Story. Aspects of the caregiver's personal life story contribute to being able to serve as a secure base for a child. Adults who recall their own parents as accepting, responsive, and available are more likely to be able to transmit those qualities as they enact the caregiver role. Adults who have experienced early loss or disruption of an attachment relationship have more difficulty providing a secure base for their offspring (Ainsworth & Eichberg, 1991). Some studies find that parents who have experienced significant loss in the recent past may behave in frightening or frightened ways that undermine the infant's ability to form a stable attachment representation (Stovall-Mcclough & Dozier, 2016).

Studies suggest that the internal working model of an attachment relationship may be transmitted across generations. Mothers and fathers draw on the model of an attachment they formed as infants and young children, which then guides their perceptions of infant cues and their own responses (Bornstein, 2012; George & Solomon, 2008). Parents' early life experiences establish patterns of reaction to the positive and negative cues they observe in their infants, thereby shaping their responsiveness and influencing the kinds of behaviors infants engage in to draw out the quality of care they need (Shah, Fonagy, & Strathearn 2010).

Contemporary Factors. Contemporary factors can influence the ability of an adult to provide a secure base for attachment. For example, some mothers experience high levels of postnatal depression. Depressed mothers are likely to be less attuned to their infants' signals, less playful, less verbally stimulating, more irritable, and generally less enthusiastic and happy as they interact with their infants. Attachment insecurity is more likely when infants' mothers are suffering from depression (Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009). The role of the child's father and the relationship between the mother and father or the caregiving partners are especially central. A partner who is supportive, involved in caregiving, and reassuring about meeting the challenges of parenting a newborn provides a context in which even mothers who have had insecure attachments themselves can thrive. On the other hand, some relationships are characterized by conflict and poor communication, in which the partner may even compete with the infant for the mother's care or impede the mother's efforts to care for her infant. Other contemporary factors that influence the caregiver's sensitivity to the infant include the caregiver's self-esteem, the degree of control the caregiver believes is necessary to have over the infant's behavior, the presence of a supportive social network that validates the person's caregiving efforts, the person's involvement in the labor market, and financial worries (Belsky, 2006; George & Solomon, 2008).

Infant Characteristics. The quality of attachment can also be influenced by the characteristics of the infant. Infants born with physical abnormalities are more likely to evoke responses of rejection or neglect from caregivers (Azar, 2012). Physical conditions such as colic can test the parents' commitment to caregiving and create a cycle of anxiety and fearfulness. Babies with colic may not find comfort in their caregivers' efforts to soothe them, and caregivers may not experience a sense of efficacy in their ability to calm their child.

Certain aspects of the infant—especially fearfulness, sociability, and the intensity of negative emotions—may influence the way the attachment relationship is established (Vaugh, Bost, & van Ijzendoorn, 2008). Infants who are irritable are often difficult for parents to respond to. Over time, some parents may respond to difficult infants harshly or by withdrawing. These behaviors may produce an insecure attachment for the infant (Putnam, Sanson, & Rothbart, 2012).

The Relevance of Attachment to Subsequent Development

The nature of one's attachment and the related internal working models of attachment influence expectations about the self, others, and the nature of relationships (Shaver, Collins, & Clark, 1996). Moreover, the formation of a secure attachment relationship is expected to influence the child's ability to explore and engage the environment with confidence, knowing that the protective "other" is near at hand. Children who experience a secure attachment are less likely to be exposed to uncontrollable stress. As the **Applying theory and Research to Life** box, The Neuroscience of Attachment suggests, the social regulation of emotion, especially management of threat and associated stress, is a major feature of a secure attachment and provides the link between supportive social relationships and health. Children who have a secure attachment experience rhythmic, meaningful, and predictable interactions that contribute to their social competences. As a result, they are *hopeful* about their ability to form positive relationships with others (Weinfield, Sroufe, Egeland, & Carlson, 2008).

Securely attached infants become preschoolers who show greater resilience, self-control, and curiosity. In contrast, infants who have a disorganized attachment are very hostile, aggressive preschoolers (Hazan, Campa, & Gur-Yaish, 2006). Results of numerous studies indicate that as they get older, children who have a disorganized attachment, especially boys, are at high risk for externalizing problems (Fearon, Bakermans-Kranenburg, van IJzendoorn, Lapsley, & Roisman, 2010).

APPLYING THEORY AND RESEARCH TO LIFE

The Neuroscience of Attachment

A growing body of research is addressing two intriguing questions: How does the brain support the attachment system? How is the brain altered in the context of social contacts related to attachment?

There is no single neural system that aligns in a one-to-one relationship with the construct of attachment. As Coan (2016) suggests, you can think of the whole brain as an attachment system that uses its hearing, vision, touch, smell, and movement sensory areas as well as memory, affect regulation, and stress/threat responses to form an integrated internal working model of the object of attachment. Many of the ideas we have introduced in the chapter thus far help to account for the way that filial affection unfolds rapidly and unconditionally in the infant.

1. The capacity to recognize the familiar emerges very early. Our discussion of habituation as an early form of learning confirms this idea. A preference for the familiar is supported by the production of dopamine. Positive stimuli act as reinforcers through the release of dopamine. We can understand that with repeated interactions with a familiar caregiver, a chain of dopamine activation takes place, reinforcing the pleasure of experiencing this familiarity and motivating the desire to experience this contact again and again.
2. The amygdala is a complex set of structures that is intimately associated with emotion, especially signs of threat. Given the importance of threat assessment for survival, it is not surprising that the amygdala can be quickly activated through sensory information. But it also sends information to the prefrontal cortex, which can result in appraisal and reinterpretation of the threat. The amygdala is especially sensitive to facial expressions, promoting the capacity for social referencing. The infant can use a caregiver's facial expressions to assess emotionally charged situations, especially fear.
3. The amygdala may tag a social interaction as emotionally salient, but the hippocampus will consolidate the memory of that interaction and preserve it in long-term memory.
4. The hypothalamus regulates many metabolic processes, linking the central nervous system and the endocrine system. The hypothalamus receives signals from the amygdala, the hippocampus, and the prefrontal cortex. When these signals suggest a threat, a sequence of neural systems, known as the hypothalamic-pituitary adrenal (HPA) axis is activated to produce cortisol. Cortisol is circulated throughout the body, influencing the following systems:
    - Blood sugar (glucose) levels
    - Fat, protein, and carbohydrate metabolism to maintain blood glucose
    - Immune responses
    - Anti-inflammatory actions
    - Blood pressure
    - Heart and blood vessel tone and contraction
    - Central nervous system activation

   In the context of caregiving behaviors, especially social soothing, the hypothalamus can regulate the production of cortisol, returning it to baseline levels. Looking at this list, you can appreciate the role of effective nurturing and secure attachment for long-term health.
5. The prefrontal cortex is connected to all systems mentioned above. It plays a role in interpreting or appraising emotional information, regulating emotional responses, directing attention, and integrating current information with long-term memory.
6. In the first 2 years, during a period of rapid production of axons, dendrites, and synapses, the neural organization that takes place is particularly sensitive to the caregiving context. Basic, largely automatic emotional assessments and related responses are gradually modulated and interpreted by voluntary cognitive control processes. But in first months of life, efforts that the caregiver makes to comfort, soothe, and respond to infant distress shape the neural pathways associated with memory of care, instigate cues for the release of hormones, and build an embodied set of expectations about the nature of this social contact (Schore, 2013; Vatička & Vuilleumier, 2012).

Two forms of attachment disorder have been identified by the DSM-5 (Attachment and Trauma Network, 2014):

1. **Reactive Attachment Disorder** – A consistent pattern of inhibited, emotionally withdrawn behavior toward adult caregivers, manifested by both of the following:
    - The child rarely or minimally seeks comfort when distressed.
    - The child rarely or minimally responds to comfort when distressed.

   A persistent social or emotional disturbance characterized by at least two of the following:
    - Minimal social and emotional responsiveness to others
    - Limited positive affect
    - Episodes of unexplained irritability, sadness, or fearfulness that are evident even during nonthreatening interactions with adult caregivers
2. **Disinhibited Social Engagement Disorder** – A pattern of behavior in which a child actively approaches and

interacts with unfamiliar adults and exhibits at least two of the following:

- Reduced or absent reticence in approaching and interacting with unfamiliar adults
- Overly familiar verbal or physical behavior (that is not consistent with culturally sanctioned and with age-appropriate social boundaries)
- Diminished or absent checking back with adult caregiver after venturing away, even in unfamiliar settings
- Willingness to go off with an unfamiliar adult with little or no hesitation

In addition to these clinical diagnoses, a third form of attachment disorder has been identified as developmental trauma disorder, to be distinguished from post-traumatic stress disorder (van der Kolk, 2005). According to experts who work in the field of stress and trauma, the symptoms associated with developmental trauma disorder occur when a child or adolescent has experienced or witnessed multiple or prolonged adverse events over a period of at least 1 year beginning in childhood or early adolescence, including:

- Direct experience or witnessing of repeated and severe episodes of interpersonal violence, and
- Significant disruptions of protective caregiving as the result of repeated changes in primary caregiver, repeated separation from the primary caregiver, or exposure to severe and persistent emotional abuse.

As a result of these experiences, children who experience developmental trauma disorder have significant difficulties regulating arousal and self-soothing, difficulties managing attention, preoccupation with threat, and difficulties managing social relationships including those with caregivers and peers.

From a life-span perspective, the quality of the attachment formed in infancy influences the formation of later relationships. Children who have formed secure attachments in infancy are likely to find more enjoyment in close peer friendships during their preschool years. In an analysis of the results of more than 60 studies of the relationship of parent–child attachment and peer relations, the quality of attachment with the mother was consistently predictive of the quality of close peer friendships well into middle school and early adolescence (Schneider, Atkinson, & Tardif, 2001). Children who have secure attachments are more likely to attribute positive intentions to peers, whereas children with anxious attachments are more likely to view peers with wariness.

The attachment construct has been used to help explain the nature of adolescent and adult love relationships as well as characteristics of adult parenting behaviors. These topics will be covered in chapter 11, Early Adulthood.

Critique of the Attachment Paradigm

The attachment paradigm and its measurement using the strange situation have significant limitations especially when viewed from a cross-cultural or comparative cultural lens. Three criticisms are discussed here; you may think of others.

Michael Newman/PhotoEdit

The attachment construct continues to be evident in adult, loving relationships. This mother and daughter enjoy physical closeness, comfort each other, and look to each other for reassurance in times of stress.

1. The strange situation analyzes the child–caregiver attachment based on how the infant copes with the stressors associated with separation from the caregiver. Although one might assume that infant–caregiver separation is a universal problem, it is much more common in some cultures than others. For example, in many parts of Asia, Africa, and South America, infants sleep with their mothers and are carried on the mother's back or side throughout the day. Close physical contact is a culture's way of conveying warmth and safety. The prolonged physical separation that would occur if a baby sleeps in a bassinet or in a separate room would be considered harsh or cruel parenting. Thus, the premise that attachment can be assessed by how well a baby copes with separation may be a poor yardstick in cultures where infant–mother separation is rare and not highly valued (Greenfield, Keller, Fuligni, & Maynard, 2003).

2. The attachment framework and the strange situation emphasize the nature of the mother–infant dyad as the prototype of an attachment relationship. Although some research has been carried out to compare attachment to mothers and fathers, or mothers and caregivers, the focus is on a dyadic attachment. However, in many cultures, the infant is cared for by a cluster or collective of older siblings, cousins, aunts, fathers, and uncles, as well as the mother and other specially designated caregivers. In these cultures, the ability of the child to feel safe and secure depends on the coordinated care of many members of the family or village rather than exclusive care by the mother. The strange situation in particular and the attachment paradigm more generally do not capture the fluid nature of this collective caregiving context and the degree to which it is effective in supporting a child's feelings of safety and security (Lewis, 2005).
3. Infant–caregiver interactions can be understood as an introduction to the nature of valued social relationships which, over time, will contribute to the child's survival and successful integration into the social community. One of the assumptions of the attachment framework is that a secure attachment provides a safe harbor from which the child feels free to explore the environment. From this view, attachment is a foundation for subsequent independence. However, autonomy, exploration, and self-reliance are not primary goals of socialization in all cultures. Societies marked by greater value for interdependence view the formation of infant attachment as a precursor to obedience, intragroup harmony, and acceptance of cultural norms and values.

Thus, while the need to ensure the survival of the young through sensitive and responsive care may be a cultural universal, the socialization goals that follow from the formation of a secure attachment may differ from one culture to the next depending upon the culture's goals, values, and traditions (Mesman, van IJzendoorn, & Sagi-Schwartz, 2016; Weisner, 2005).

FURTHER REFLECTION: *Explain the evolutionary basis for the attachment behavior system. In this light, hypothesize why very small babies might be vulnerable to the formation of insecure attachments.*

Describe the concept of sensitive caregiving. How might contemporary life events disrupt an adult's ability to provide sensitive care?

Emotional Development

OBJECTIVE 6 Examine the nature of emotional development, including emotional differentiation, the interpretation of emotions, and emotional regulation. Analyze the concept of temperament as an organized aspect of emotional reactivity.

Emotional development during infancy can be understood along four dimensions. First, new emotions emerge. Infants express these emotions at different levels of intensity—for example, from a whimper or fussy noise to a full-blown angry rage, or from a happy cooing gurgle to outright laughter. Second, with cognitive maturation, a child interprets events differently. New emotions may become attached to familiar situations. An experience that may once have caused wariness, such as a new toy or a loud noise, may become a source of excitement or joy as the child gains a new understanding of the situation. Third, children develop strategies for regulating their emotions so that they are not overwhelmed by emotional intensity. Fourth, emotions serve as a channel for adult–infant communication.

Emotional Differentiation

New emotions gradually emerge during the first 2 years of life. Peter Wolff (1966) described seven states of arousal in newborn infants: regular sleep, irregular sleep, periodic sleep, drowsiness,

Skreidzeleu/Shutterstock.com
Skreidzeleu/Shutterstock.com

At 3 months of age, infants can communicate their emotional state using different facial expressions. Sensitive caregivers can detect happiness, excitement, wariness, sadness, and frustration.

alert inactivity, waking activity, and crying. Each is characterized by a different pattern of breathing, muscle tone, motor activity, and alertness. In these states, one observes the earliest distinct emotions of distress (*crying*), interest (*alert inactivity*), and excitement (*waking activity*). A newborn's state of arousal influences the capacity to respond to the environment. Changes in arousal also prompt responses from caregivers. Crying usually brings an effort to comfort or soothe. Visual alertness is likely to prompt social interactions with caregivers who use a variety of strategies to sustain contact such as smiling, making cooing sounds, or shaking a toy or rattle.

Crying is an especially important emotional expression that contributes to the infant's survival. Until about 6 or 7 months of age, the infant's mobility is quite limited. The cry is one of the primary signals available that will bring the caregiver to the infant. Infant cries vary in pitch as well as in tempo and duration. Adults have measurable emotional reactions to infant crying, including changes in heart rate, breathing, and perspiration, which indicate that the cry serves as a stressor. Studies from laboratory and natural field settings and across cultures suggest that high-pitched cries are considered more upsetting to the caregiver and are treated as a signal of a more urgent need than are low-pitched cries. Moreover, information is contained in the pauses between cries. Cries that involve shorter pauses between crying sounds are perceived by adults as more arousing and unpleasant (Groh & Roisman, 2009; Zeskind, Klein, & Marshall, 1992).

Emotional responses during the first month are closely tied to the infant's internal state. Physical discomfort, arousal, pain, and changing tension in the central nervous system are the major sources of emotions. During the period from 1 to 6 months, emotions begin to reflect the infant's awareness of features of the environment. Babies smile at familiar faces; they show interest in and curiosity about novel stimuli. They express rage when nursing is disrupted or when they are prevented from viewing an activity they have been intently watching.

From 1 to 6 months, the intensity of emotional expression becomes more varied. For example, four different kinds of infant smiles have been observed: the simple smile in which a baby's mouth curves upward at the corner; the Duchenne smile, which involves crinkling eyes, raised cheeks, and an open, smiling mouth; the play smiles in which the jaw drops and the mouth stays open; and the duplay smiles in which the jaw drops and the cheeks are raised (Fogel et al., 2006). The simple smile is considered a signal of happy social engagement, whereas the Duchenne, play, and duplay smiles reflect different levels of intensity in play that accompany such activities as tickling, peek-a-boo, and playful interactions with familiar caregivers.

The period from 6 to 12 months reflects a greater awareness of the context of events. Emotions of joy, anger, and fear are tied to a baby's ability to recall previous experiences and to compare them with an ongoing event. These emotions also reflect the ability to exercise some control over the environment and frustration when goals are blocked. Fearfulness, assessed several times from 4 to 12 months, increases steadily over the first year. Babies who are less fearful at 4 months show a steeper increase in fear than babies who are already quite fearful at a very young age (Gartstein et al., 2010).

The dimension of wariness–fear becomes more differentiated during the second year. Wariness is viewed as an early feature of the attachment process, especially as it relates to stranger anxiety at about 6 months and separation anxiety at about 9 months. Fear responses are relatively rare among young infants. It may be that fear needs to be learned as babies gain experiences that result in the appraisal of threat. Fear of a more nonspecific form begins to be observed during the second year. Babies begin to anticipate negative experiences and express fear of objects or events that have been associated with negative experiences in the past. In the image on the left below, the fear response is evoked when a nurse returns for the second of two inoculations. In some instances, as in the image on the right, one sees the expression of fear blended with surprise, as when a novel toy emits a loud noise or a dog makes a sudden move toward the infant (Sullivan & Lewis, 2003).

By the end of the first year, the extent of an infant's negative emotions, such as irritability and fear, are influenced by the caregiver's depression and anxiety. The impact of maternal depression on infants' psychosocial development has received a great deal of attention in the literature, demonstrating that there are

A fear expression in response to approach of a nurse following inoculation (a) and a fear blend in response to the sudden appearance of a stimulus (b).

distinct differences in the emotional expressiveness and social engagement of infants of depressed mothers. Higher levels of maternal depression and anxiety in infancy are linked to greater increases in fearfulness at the end of infancy, and more symptoms of anxiety at age 2 (Gartstein et al., 2010). Positive emotions are not as clearly tied to the caregiver's characteristics (Pauli-Pott, Mertesacker, & Beckman, 2004).

Emotions that are observed during the second year of life, 12 to 24 months—especially anxiety, pride, defiance, and shame—suggest an emerging sense of self. Infants recognize that they can operate as causal agents. They also begin to respond to the emotions of others. They can give love to others through hugs, kisses, and tender pats. They can share toys, comfort another distressed infant, and imitate another person's excitement. In becoming a more distinct being, an infant achieves a new level of awareness of the capacity to give and receive pleasure as well as the vulnerability of self and others.

Emotions as a Key to Understanding Meaning

An infant's emotional reactions provide a channel for determining the meaning the child is giving to a specific situation. Often, these reactions are studied by the systematic coding of facial expressions. One example of how emotions provide a window on meaning comes from a study of infants in an operant conditioning experiment. Infants at ages 2, 4, and 6 months were observed while they learned an operant arm-pulling task. A string was attached to the infant's wrist. When the string was pulled, it activated a switch that turned on a color slide of an infant smiling accompanied by the sound of children singing the *Sesame Street* theme song. During the learning phase, pulling the string produced the visual and auditory stimulus. During the extinction phase, nothing happened when the string was pulled. Even as young as 2 months old, the babies' expressions changed from interest and enjoyment during the learning phase to anger and sadness during the extinction phase. The study illustrates that infants' anger is associated with violation of their expectations and that expressions of interest and enjoyment are associated with learning and increased control (Sullivan, Lewis, & Alessandri, 1992).

An infant's smile can have a wide variety of meanings and can be produced in response to many stimuli. *Social smiles* begin to be observed at about 5 weeks of age. These smiles are first produced in response to a wide range of stimuli: familiar faces and voices (especially the mother's), strangers, and nonhuman objects. Games such as tickle and peek-a-boo bring on open-mouth smiles and laughter (Fogel et al., 2006). The social smile conveys both recognition of familiarity and an invitation to further communication or interaction.

The *cognitive smile* develops alongside the social smile. Infants smile in response to their own behaviors, as if they were expressing satisfaction with their accomplishments or self-recognition. In a study of infants over the period from 7 to 20 weeks, babies were observed to show the *coy smile*—smiling while averting their gaze—when they were successful in getting attention or renewing attention from an adult (Reddy, 2000). As evidenced in the string-pulling task described previously, infants make a *mastery smile* when they are able to make something happen.

In the second year of life, smiling is associated with a primitive form of *humor*. Babies smile when they recognize an incongruity, such as seeing their mother drinking from a baby bottle or crawling on her hands and knees. They also smile and laugh when they violate a caregiver's expectations. These smiles suggest that the baby appreciates something about the discrepancy between what is being presented and what is normally observed (Loizou, 2005).

The Ability to Regulate Emotions

Emotional regulation refers to a variety of processes that allow infants to control the intensity of their emotional state and reduce feelings of distress. These abilities, which mature over the first 2 years, have important implications for a child's successful social participation in preschool and later childhood (Calkins & Leerkes, 2011). Infants develop a range of techniques for coping with intense emotions, both positive and negative. Even newborns have some strategies for reducing the intensity of distress, such as turning the head away, sucking on their hands or lips, or closing their eyes. As infants gain new motor coordination and control, they can move away, distract themselves with other objects, or soothe themselves by rocking, stroking, or thumb sucking (Kopp, 1989). One study compared 3-, 5-, and 7-month old infants as they reacted to their mother and their father who were showing them the "still face." Infants who looked away or who engaged in some kind of self-soothing activity showed at decrease in distress; infants who engaged in intense motor activity showed an increase in distress (Ekas, Lickenbrock, & Braungart-Rieker, 2013). There are many instances when infants are not able to regulate the intensity of their emotions. Researchers who work with infants often note the number of babies who had to be eliminated from their study because they simply could not be calmed enough in the experimental procedure to attend to the task. The way an infant reacts to environmental stimuli and the intensity of that reaction is often conceptualized as a reflection of the concept of temperament.

Temperament.

Temperament is a theoretical construct that refers to relatively stable characteristics of response to the environment and patterns of self-regulation (Putnam, Sanson, & Rothbart, 2012; Thomas & Chess, 1980).

> Temperament traits are early emerging basic dispositions in the domains of activity, affectivity, attention, and self-regulation, and these dispositions are the product of complex interactions among genetic, biological, and environmental factors across time. (Shiner et al., 2012, p. 2)

Temperament is a significant source of individual differences. When we describe babies as active, cheerful, quiet, or fussy, we are making reference to what scholars study as temperament. One of the underlying questions is the extent to which infant temperament is predictive of adult personality. Although aspects of temperament that might be observed in infancy are quite different from the features of adult personality, it is possible that features of temperament, such as inhibition or wariness, and features of adult personality, such as shyness or social anxiety, may be reflections of a common underlying dimension. Theorists have offered different views about the specific features of temperament and what accounts for the stability of these features over time

Table 5.8 Three Types of Infant Temperaments

Type	Description	% of Total Sample
Easy	Positive mood, regular body functions, low or moderate intensity of reaction, adaptability, positive approach rather than withdrawal from new situations	40
Slow to warm up	Low activity level, tendency to withdraw on first exposure to new stimuli, slow to adapt, somewhat negative in mood, low intensity of reaction to situations	15
Difficult	Irregular body functions, unusually intense reactions, tendency to withdraw from new situations, slow to adapt to change, generally negative mood	10

Note: Some researchers prefer terms such as flexible and active, cautious, and feisty rather than easy, slow to warm up, and difficult, which have judgmental connotations.

Source: From "The Origin of Personality," by A. Thomas, S. Chess, and H. Birch, 1970, *Scientific American*, 223, pp. 102–109.

(Vaughn & Bost, 2016). The following section reviews four views of temperament.

Dimensions of Temperament. Thomas, Chess, and Birch (1970; Thomas & Chess, 1977) used observations of nine dimensions to classify infants into three temperamental groupings: *easy*, *slow to warm up*, and *difficult*. Table 5.8 summarizes the characteristics of each of these temperaments and the percentages of the sample that could be clearly identified as one of the three types. Roughly 35 percent of the sample could not be classified. Some researchers use different labels to describe these types, reflecting an understanding that some aspects of infant behavior are difficult for some parents but easy for others. In newer work, the types are labeled "resilient," "undercontrolled," and "overcontrolled," terms that capture features of self-regulation, and seem less judgmental (Caspi & Shiner, 2006).

Buss and Plomin (1984/2015; 1986) identified three aspects of temperament—activity level, sociability, and emotionality— that they thought were influenced largely by genetic factors. Further work has included impulsivity, a trait comprising difficulties with emotional and behavioral control, persistence, and planfulness as showing a strong genetic basis (Gagne & Saudino, 2010; Saudino & Zapfe, 2008). Patterns of electrical activity in the frontal cortex in infancy have been associated with individual differences in these features of temperament, particularly distinguishing between babies who are more able to regulate their emotions, who are easily soothed, and who seem to be relatively positive as contrasted to the babies who are easily distressed, difficult to soothe, and have difficulty focusing their attention (Schmidt, Fox, Perez-Edgar, & Hamer, 2009). These dimensions—especially emotionality and activity level—show modest stability over adjacent periods of infancy and toddlerhood (Henderson, Fox, & Rubin, 2001). Genetic factors appear to account for stability in temperament across different settings (e.g. laboratory and home). However, genetics and environment also interact, especially when considering possible prenatal influences on development, and the differential sensitivity of infants to nurturing versus harsh parenting (Braungart, Plomin, DeFries, & Fulker, 1992; Goldsmith & Campos, 1986; Goldsmith et al., 1987; Shiner et al., 2012; Wilson & Matheny, 1986).

Another view of temperament focuses on the construct of **behavioral inhibition**, a combination of fearfulness, a low threshold for arousal in the presence of novel or unusual stimuli, and general cautiousness. A method of assessing behavioral inhibition involves presenting infants with a set of unusual stimuli and observing their reactions. Some infants seem to think this is great fun. They smile, coo, and respond with positive excitement. Other infants get very distressed. They cry, struggle, arch their backs, and try to escape the situation. These early reactions in the laboratory setting at 4 months of age are predictors of toddler behavior. The infants who react positively to the novel stimuli are likely to become active, busy, exploratory toddlers. The infants who react with distress to the novel stimuli are likely to become fearful, shy, and socially wary toddlers (Kagan & Snidman, 2004).

Rothbart (1981; Rothbart & Bates, 2006) characterized temperament as "constitutionally based individual differences in reactivity and self-regulation in the domains of affect, activity, and attention" (Rothbart & Bates, 2006, p. 100). Rothbart's research led to the identification of three overarching dimensions of temperament: surgency/extroversion, negative affectivity, and effortful control. These dimensions, viewed as present in infancy, undergo maturation associated with the emerging neural basis for attention and self-regulation. Studies of mothers' and fathers' observational ratings of their infants support the stability of these dimensions from infancy to toddlerhood, with the exception that orienting/regulating is observed in very young infants as the precursor to effortful control in toddlers (Casalin, Luyten, Vliegen, & Meurs, 2012).

A child's temperament influences the tone of interactions, the frequency with which interactions take place, the way others react to the child, and the way the child reacts to the reactions of others. Highly active, sociable children are likely to initiate interactions and to respond positively to the attention of others. More passive, inhibited, or fearful children will be less likely to initiate interactions and may withdraw when other children or adults direct attention to them. There is growing concern that infants and toddlers who are temperamentally shy, fearful, and readily distressed by novel or unfamiliar situations may be vulnerable to subsequent difficulties regulating anxiety and depression (Moffitt et al., 2007).

The kind of caregiving a child receives will depend in part on the parental context. For example, Thomas and Chess (1977, 1986) found that when parents were calm and allowed their difficult children to adapt to novelty at a leisurely pace, the children grew more comfortable and had an easier time adapting to new routines. However, if parents were impatient and demanding, then their difficult children remained difficult and had a hard time adjusting to new situations as they grew older. A mother's age, her economic resources, the nature of the neighborhood where she lives, and characteristics such as depression, stress, or a sense of parenting efficacy might each influence how patient and supportive a mother may be with a child who has an emotionally negative or irritable temperament (Paulussen-Hoogeboom, Stams, Hemranns, & Peetsma, 2007).

Cultura Creative/Alamy Stock Photo

Is this baby showing evidence of a difficult temperament or is the protest a result of the father's lack of attention? What observations would you need to make in order to answer this question?

Child outcomes are understood as a product of child temperament and parenting strategies (Rothbart & Bates, 2006). Many studies emphasize the relevance of the fit or match between the parent's temperament and that of the child (Rettew et al., 2006). Depending on the caregiving they receive and the environments they encounter, shy children can become sociable, fearful children can become secure explorers of their surroundings, and highly exuberant children can develop considerable self-control (National Research Council and Institute of Medicine, 2000,p. 389). In all likelihood, temperamental characteristics are modified as they come into contact with socialization pressures at home and at school, as well as with new internal capacities to regulate behavior.

A few examples of this kind of interaction follow:

- Gentle, low-power discipline techniques are more effective in socializing infants who are relatively fearful and inhibited; these techniques do not work well with temperamentally fearless infants who respond better to socialization strategies that emphasize positive feelings between the mother and child (Kochanska, Aksan, & Joy, 2007).
- Children who are fearful are more likely to be inhibited with their peers when their mothers are overprotective, but more confident with their peers when their mothers are reassuring and supportive of the child's autonomy (Rubin, Hastings, Stewart, Henderson, & Chen, 1997).
- Parental use of harsh punishment is not predictive of aggressive behavior for children who are flexible and low in reactivity but is strongly linked to aggressiveness among children who are inflexible and highly reactive (Patterson & Sanson, 1999).

These and other findings create a complex picture of differential sensitivity and reactivity to the features of the caregiving environment. Children differ in the extent to which they detect and react to environmental demands or threats (Moore & Depue, 2016). A modest level of parental dominance or assertiveness may be frightening and intimidating for a child with high behavioral inhibition, and completely insignificant for a child with low behavioral inhibition (Gilissen et al., 2007). Consider the role of temperament in the case study on the Cotton family.

— **CASE STUDY** The Cotton Family —

Nancy and Paul Cotton are a professional couple who gave birth to their first child, Anna, after they had been married for 7.5 years.

Nancy said, "We wanted a baby but couldn't decide when to have one. Finally we realized that we could not control everything, or time things perfectly. No one can predict the future. So we finally decided to go ahead and have a child as soon as possible. … By the time we had Anna, I was thirty-three, and our marriage and careers were established. We felt secure.

"Being an optimistic person, I guess I expected nirvana. Anna was difficult to deliver, and breastfeeding was a nightmare. Every time she nursed, it hurt. But I didn't want to miss the opportunity. I was so determined. I used a stopwatch to make sure Anna got enough milk, and I gave her a pacifier for recreation. When she was five weeks old, I went off to our summer house on Martha's Vineyard. I wondered if it was the right decision because there was less in the way of family and friends for support. But we worked things out together that summer. She was energetic from the first, and I was constantly sleep-deprived, but we were oh! so close. I found ways to make it easier for us. I used the 'Swyngomatic' so that I could eat a warm supper every once in a while, and I learned to give Anna pacifiers or bottles to soothe herself."

Paul interjected: "She was like a miracle to me. She was fabulous! Miraculous! She even looked like me. I did as much for her as Nancy did, not out of guilt, but because I couldn't keep my hands off her. I took her with me everywhere when I was off work. At the Stop-and-Shop, all the ladies crowded around me, 'How do you do it? You're so good with her!' I learned all about babies from her. I can bathe a kid faster than anyone in the world."

"Anna fit," said Nancy. "From the time she was born, we'd pick her up and just go. As you can see, going is pretty important in our family, and Anna thrived on it. We were not the only ones who enjoyed her; my own mother thought she was fabulous. She took care of her part-time after I went back to work. I had a chance to see my mother be loving and kind, a good mother to Anna. It was like reliving my own childhood—another kind of miracle. You see, I'd had a sister, Ginny, who had died. Anna gave my mother an opportunity to heal the pain of Ginny's death. This was true for me, too."

CASE ANALYSIS Using What You Know

1. Describe Anna's temperament. What problems might the Cotton family have faced if Anna had been a more passive, reserved, and inhibited child?
2. Evaluate the ways that Anna was expected to adapt to the Cotton family lifestyle.
3. List some of the challenges Nancy and Paul faced as new parents. How did they cope with these challenges?
4. Describe and assess Paul's enactment of the father role. Describe and assess Nancy's enactment of the mother role. How well do they match the features of sensitive parenting?
5. Anna seems to be influencing the well-being of her mother, father, and her grandmother. What impact does Anna have on each of these family members?

How Caregivers Help Infants Manage Their Emotions. One of the most important elements in the development of emotional regulation is the way caregivers assist infants to manage their strong feelings. Caregivers can provide direct support when they observe that a child is distressed. They may cuddle, hug, rock, or swaddle a baby. They may offer food or a pacifier to the baby or nurse her as a means of comfort. Through words and actions, the caregiver may help a child interpret the source of the stress or suggest ways to reduce the stress.

In a longitudinal study of maternal comforting strategies, mothers were observed as they tried to comfort their children following an inoculation at 2 and 6 months of age. The intensity and duration of infant crying decreased over this 4-month period. At the younger age, mothers used affection and soothing as comforting strategies when their babies cried after the shot; at 6 months, they used vocalization and distracting strategies more often, taking advantage of the infant's more developed capacities for attention and playfulness. For all levels of infant distress, the most effective method of soothing was a combination of holding/rocking and vocalizing, combining the sense of touch and the rhythmic movement of rocking with the calming features of the mother's voice (Jahromi, Putnam, & Stifter, 2004).

Concern has focused on babies who show intense negative emotionality early in infancy. Babies who show high levels of motor activity and who cry a lot at 4 months of age have been found to show high levels of wariness, fearfulness, and shyness at later ages. Babies who show high levels of fearfulness appear to be at risk for later problems with social anxiety (Buss, 2011). Studies have analyzed individual differences in negative emotionality and the family characteristics that might be associated with changes in negativity over the first year of life (Calkins & Howse, 2004; Pauli-Pott et al., 2004). In a longitudinal analysis of the relationship of parenting environments and infant temperament among a sample of over 2,000 Canadian families, exposure to more positive parenting reduced behavior problems in children with difficult/undercontrolled temperaments. Contextual factors including neighborhood problems, neighborhood cohesion, social support, and maternal depression influenced the ability of parents to provide positive, sensitive parenting for those infants with more undercontrolled temperaments (Gallitto, 2015).

Caregivers' approaches to infant emotional regulation vary with the culture (Kitayama, Karasawa, & Mesquita, 2004; Mesquita, De Leersnyder, & Albert, 2014). In some cultures, caregivers regulate emotions by preventing a child from being exposed to certain arousing situations. Japanese mothers, for example, try hard to prevent their children from being exposed to anger and avoid frustrating them. Furthermore, parents rarely express anger to their young children, especially in public. Thus, Japanese parents try to regulate anger by minimizing the child's experiences with it. Cultural values influence how mothers respond to infants' distress and what they teach their babies about how to regulate feelings of wariness, fear, and anxiety.

Infants achieve emotional regulation by observing emotional reactions of others. Children observe anger, pride, shame, or sadness in others, often in response to their own emotional expressions. For example, Connie stumbles and falls in trying to take a step on her own. She looks up at her mother. If her mother looks upset and frightened, Connie may begin to cry. On the other hand, if her mother laughs or speaks to her in a comforting tone, Connie may get up and try again. Children can be distracted from their sadness by seeing laughter and joy in someone else. Through empathy, they can reduce their angry feelings toward someone else by seeing how sad or frightened the other person is.

As children understand the consequences or implications of a situation, they have new motives for regulating or failing to regulate their emotions. Children may extend or expand their signals of distress if they think it will help them achieve their goals, such as special attention or nurturing. Children may try to disguise their distress if they think it will provoke additional pain. Emotional regulation, like emotional signaling, takes place in an interpersonal context.

Emotions as a Channel for Adult-Infant Communication

Emotions provide a two-way channel through which infants and their caregivers can establish **intersubjectivity**. An infant has the capacity to produce a range of emotional expressions, including fear, distress, disgust, surprise, excitement, interest, joy, anger, and sadness. Parents and other caregivers rely on facial, vocal, and behavioral cues related to these emotions as ways of determining an infant's inner states and goals, and responding to them. Using techniques for recording neural electrical activity, studies find that infant smiles and cries stimulate different areas of the caregiver's brain. Both biological and adoptive mothers react with special sensitivity to their infant's crying (Doi & Shinohara, 2012).

The mirror neuron system provides infants and adults with the capacity to link seeing and doing. This system is activated both when we perform an action and when we see someone else perform that action. Thus it creates an early neural bridge for social understanding of behavior. Mirror neurons support an infant's capacity to imitate adult expressions, and for adults to recognize and interpret infants' expressions. Mirror neuron processes are needed for social connection but are not adequate for the co-construction of meaning. This is gradually supplemented by joint attention, shared emotional referencing, and the attached association of positive or negative reactions that provide approach and/or avoidance cues and create a framework for shared values (Rochat & Passos-Ferreira, 2009).

Babies can detect and differentiate the affective expressions of others including fear, anger, happiness, sadness, and surprise. They can recognize facial expressions at 4 months of age, but they require further time to understand the meanings of these expressions (Grossman, 2013; Kaneshige & Haryu, 2015). In cycles of interaction, responsive caregivers monitor changes in a baby's affect as a way of determining whether their interventions are effective (Meins, 2011).

Think of a 6-month-old baby who wants a toy that is out of reach. The baby waves her arms in the direction of the toy, makes fussy noises, and looks distressed. As her father tries to figure out what the baby wants, he watches her expressions in order to discover whether he is on the right track. Parents who are attuned to this form of communication are more likely to help babies to achieve their goals, and babies are more likely to persist in attempts to communicate because they have experienced success in such interactions. Through a shared repertoire of emotions, babies and their caregivers are able to understand one another and create common meanings. Thus, emotional expression becomes a building block of trust (Trevarthen & Aitken, 2001).

Social Referencing. One of the most notable ways that infants and adults have of co-constructing their reality is the mechanism of **social referencing** in which infants gather information about a situation or an object by assessing their parent's or caregiver's reactions. Social referencing involves three coordinated processes: (1) The infant coordinates attention between the adult and an ambiguous object or situation; (2) the infant understands that the adult's emotional reaction refers to the specific object or situation; (3) the infant uses the information from the adult's emotional reaction to guide behavior toward the object (Feinman et al., 1992; Hornik & Gunnar, 1988; Murray et al., 2008). By 12 months of age, infants can draw upon all of these abilities to use the emotional responses of another person to guide their own behavior (Carver & Vaccaro, 2007). They often use their mothers as a *social reference*, but other adults can serve this function as well. As infants approach an unfamiliar adult, an ambiguous situation, or a novel object, they look to their mother and use her facial expression or verbal expressions as a source of information about the situation. If the mother expresses wariness or a negative emotion, the infant is more likely to withdraw or to explore with caution. On the other hand, if the mother expresses a positive emotion, the infant is more likely to approach the situation or the unfamiliar person with confidence. By 12 months of age, infants consistently use this mechanism to try to appraise an ambiguous situation (de Rosnay, Cooper, Tsigaras, & Murray, 2006; Rosen, Adamson, & Bakeman, 1992).

In an extension of the social referencing concept, researchers wondered whether infants could gather information by observing how adults interacted with each other in relation to an object (Repacholi & Meltzoff, 2007). In an experimental situation, infants observed while one adult (the experimenter) performed specific activities with an object and a second adult (the emoter) expressed either an angry or a neutral reaction to the first adult. For example, the angry adult might say to the experimenter who was demonstrating an activity with an object, "That's aggravating! That's so annoying," while speaking in an angry tone of voice and using angry facial expressions. Then the infants were given an opportunity to touch the object while the experimenter and the emoter sat quietly in the room. Infants who observed the angry emoter were less likely to imitate the activity, slower to touch the object, and more likely to look at the angry adult who remained in the room, even though the adult was now calm and neutral in behavior. In the angry emoter condition, the infants had fewer positive facial expressions during the time when they were allowed to explore the object. The results of this research suggest that infants can gather and retain information about how to interact with objects in their environment based on what they observe of the emotional reactions of others to these objects, even when the responses are not directed toward them.

Social referencing illustrates how members of a cultural group build a shared view of reality during infancy (Halberstadt & Lozada, 2011). Infants actively request information by looking to their mothers or other adults. They also eavesdrop on adults, watching and listening to the emotional tone of their interactions. The adult's expression, either positive or negative, cues the infant about whether to approach or withdraw. In an experimental study, it was demonstrated that infants could detect the stress level of their mothers, which in turn created heightened stress in the infants. This research illustrates the role of emotional reciprocity and potential

Emotions provide a channel of communication before speech and language. The exchange of playful laughing and smiling is an early form of conversation.

contagion, especially negative of emotions, in the caregiver–infant dyad (Waters, West, & Mendes, 2014).

Infants reduce their uncertainty and begin to appraise their world in the context of the emotional responses of their caregivers. You can probably imagine the wide range of objects and situations that can be evaluated through this mechanism. Foods, toys, people, animals, sounds, plants, and objects of all sorts can be discerned as positive and approachable or negative and a cause for wariness. Depending on the cultural outlook, infants in different societies will begin to categorize their experiences differently based in part on these early appraisals derived from social referencing.

FURTHER REFLECTION: Explain how infants and caregivers use emotional communication to create meaning. Give some examples that reflect positive and negative emotion states.

The Psychosocial Crisis: Trust Versus Mistrust

OBJECTIVE 7 Explain the psychosocial crisis of trust versus mistrust; the central process through which the crisis is resolved, mutuality with the caregiver; the prime adaptive ego quality of hope; and the core pathology of withdrawal.

At each stage of life, the psychosocial crisis is expressed as a struggle between the positive and negative poles of a critical dimension. In infancy, the specific nature of the crisis—trust versus mistrust—focuses on the fundamental nature of an infant's sense of connection to the social world.

Trust

In adult relationships, **trust** refers to an appraisal of the availability, dependability, and sensitivity of another person. Trust emerges in the course of a relationship as one person discovers those traits in another person. As the level of trust grows, the partners may take some risks by disclosing information or feelings that may lead to rejection. Relationships that endure through periods of risk grow in feelings of trust. However, trust is more than a summary of the past: It is a faith that the relationship will survive in an unpredictable future. This faith begins in infancy. A trusting relationship links confidence about the past with faith about the future.

For infants, trust is an emotion—a positive state of confidence that their needs will be met and that they are valued. Trust is inferred from the infant's increasing capacity to delay gratification and from the warmth and delight that are evident in interactions with family members. This sense expands from trust of the immediate figures in the social environment to trust in the supportiveness and responsiveness of the broader social and physical world. Infants also learn to trust their sensory systems as they process stimulation from the environment. Thus, the sense of trust extends to learning to trust oneself.

The sense of basic trust is related but not identical to Bowlby's concept of attachment. Attachment refers to the behavioral system that ensures safety and security for the infant. Over time, the internal representation of the attachment relationship generalizes to other relationships, especially where issues of intimacy and protection are relevant. Trust is a broader, more abstract construct. It not only refers to the infant–caregiver relationship but also includes the orientation of the infant to the wider social network of trustable and caring others. As such, it establishes the infant's first model or way of thinking about social integration. Trust becomes a basic orientation toward the self and others; it conveys a belief that "I am safe and loved; I can extend my self toward others and count on them to be dependable and caring."

Infants establish an assessment of the central social figures in their world as trustable or untrustable; they also achieve a sense of their own value and trustworthiness. Over time, a basic sense of trust expands to a general sense of optimism about how one expects to be treated by others and about one's ability to cope with life's challenges. Trust is an integrating force that helps synthesize emotions, cognitions, and actions under conditions of uncertainty, allowing the person to pursue goals with a belief that things will work out well.

Given the key role of trust in forming and sustaining human social bonds, it makes sense to think that there is a biological basis for trusting in interpersonal interactions. Recent research has identified the role of **oxytocin** in the neuroscience of trust. Oxytocin, a hormone that plays a key role in social attachment, produces a general sense of calm relaxation, reducing wariness and increasing approach behavior (Baumgartner et al., 2008).

It is likely that positive social interactions stimulate the production of oxytocin. When a person perceives a combination of certain interpersonal cues such as facial expressions, especially smiling and laughter, rhythmic gestures, and tone of voice in a specific context, oxytocin is released. The release of oxytocin then triggers a set of neural networks that reduces wariness and fear of others and increases willingness to trust the other person (Damasio, 2005; Kirsch et al., 2005; Mayo Clinic, 2014).

Mistrust

During infancy, experiences of **mistrust** can arise from at least three sources: infant wariness, lack of confidence in the caregiver, and doubt in one's own lovableness. First, wariness, one of the earliest infant emotions, is linked initially to at least two infant reflexes, the startle response in reaction to loud noises and the Moro reflex in response to sudden loss of support (see Table 5.2). All infants are prewired neurologically to be alert to certain environmental dangers. Infants are able to use sensory information, especially the ability to interpret facial expressions and the ability to differentiate auditory cues, to assess interpersonal anger or threat. By 6 months of age, most infants show evidence of stranger anxiety, another indication of normal capacities for wariness. Two of the caregiver's functions are to minimize the infant's exposure to stimuli that evoke these responses and to comfort and reassure the infant after exposure to threatening stimuli.

Second, babies can lack confidence in the good intentions of others. Most parents contribute to experiences of mistrust because they inevitably make some mistakes in responding to their infant's signs of distress, particularly when the baby is young. They may first try the bottle, and, if the crying continues, they may change the diaper, give water, move the baby to another room, or put the baby to bed—trying a variety of things until something works.

Aspen Photo/Shutterstock.com

Molly can't get her mother's attention. Her mother is worn out and unable to make any appropriate response to Molly's distress. Over time, this inability to evoke a parent's caring response can generate mistrust.

Over time, however, sensitive caregivers learn to interpret their child's signals correctly and respond appropriately, thereby fostering the infant's sense of trust in the environment.

Some caregivers are unable to identify their infant's needs or frequently respond inappropriately to them. Others are indifferent or unusually harsh. Under conditions of maltreatment, seeds of doubt may grow about the trustworthiness of the environment. Abused infants become especially sensitive to cues that suggest hostility or anger in their environment, and are more likely to fixate on those cues, even when the threat has passed (Pollak, 2008).

Infants are not only aware of threats expressed toward them but are also sensitive to expressions of anger or hostility among other members of the household. Infants are attuned to angry, negative interactions that, at some level, threaten their security. Under conditions of interpersonal conflict, infants may try to intervene by crying or by sidling up to one of the adults; or they may try to escape by crawling away. Chronic exposure to interpersonal conflict creates a level of insecurity in the child who may feel that needs cannot be met when the adults in the family, especially attachment figures, are engaged in angry interactions with each other (Davies & Woitach, 2008).

Third, babies experience the power of their own rage. In some children, self-regulatory abilities are poorly developed, which leads to frequent outbursts of negativity and frustration. They may learn to doubt their own lovableness as they encounter the intensity of their own capacity for anger.

Feelings of doubt or anxiety about the bond of trust are more common than may have been expected. About one third of American infant–mother pairs who have been systematically observed show evidence of an insecure attachment. Cross-cultural research provides further evidence that a significant proportion of infants have difficulty deriving emotional comfort or security from their caregivers (Mesman, van IJzendoorm, & Sagi-Schwartz, 2016; Posada et al., 1995; van IJzendoorn & Kroonenberg, 1988).

In addition to the mistrust that emerges in the context of inconsistent, unresponsive, or harsh caregiving, there are cases in which the mother–infant relationship is disrupted. This can happen in conditions of war, parental imprisonment, parental death due to disease or accident, or lengthy hospitalization. In all these situations, an infant is at risk for experiencing a strong sense of mistrust.

Mistrust may manifest itself in the infant by withdrawal from interaction and by symptoms of depression and grief, which include sobbing, lack of emotion, lethargy, and loss of appetite. It may also be revealed later on in development in the expressions of interpersonal distress observed in the angry, anxious, and resistant behaviors of children with insecure attachments or in the inability to form close, satisfying relationships with others as adolescents and adults. Mistrust may provide a foundation for the emergence of a negative scheme about the self—a scheme that is elaborated over time by defining the self with a cluster of closely related, negative attributes such as cautiousness, nervousness, or introversion (Malle & Horowitz, 1995).

All infants experience some aspects of mistrust, either as a result of mismatches between their needs and the caregiving strategies they receive or as a product of their own difficulties in modulating strong feelings of wariness or anger. Just as there is a neurobiological basis for trust in the production of oxytocin, another brain-stimulating chemical, vasopressin may cause suspicion and trigger social anxiety or aggression (Neumann & Landgraf, 2012). The resolution of the crisis in the direction of trust reflects a biopsychological achievement in which infants are able to minimize their wariness of the environment and regulate their own anxiety.

Over the life span, the sense of trust is transformed and provides an operating principle that guides a person's daily life and relationships with others. The sense of trust is essential for the maintenance of complex organizations and communities. Parents trust schools to educate their children; consumers trust manufacturers to produce safe products; banks trust customers to pay back their loans. The nature of social life is built on hopefulness about positive transactions that will take place in an uncertain future (Cook, Levi, & Hardin, 2009). Among older adults who have a strong sense of trust, many of life's disappointments and complexities are minimized by a growing religious faith. Their basic sense of trust evolves into a powerful belief in a great source of goodness and love in the universe, a force that can transcend the pain of daily tragedies and give integrity and meaning to their dying as well as to their living (Erikson et al., 1986).

The Central Process for Resolving the Crisis: Mutuality with the Caregiver

To resolve the crisis of trust versus mistrust, an infant must establish **mutuality with a caregiver**. Mutuality is a characteristic of a relationship. Initially it is built on the consistency with which the caregiver responds appropriately to the infant's needs. The caregiver comes to appreciate the variety of an infant's needs, and the infant learns to expect that personal needs will be met. Within families, the establishment of mutuality differs with each child, depending on infant characteristics and parental responses (Deater-Deckard & O'Connor, 2000).

An infant and a caregiver learn to regulate the amount of time that passes between the expression of a need and its satisfaction. Bell and Ainsworth (1972) observed mothers' responses to infant crying during the first year of life. Over the course of the year, the infants' crying decreased, and the mothers tended to respond more quickly to their cries. This finding suggests a process of mutual adaptation by mothers and infants. Some mothers came quickly and ignored few cries. Other mothers waited a long time and ignored much of the crying. The longer mothers delayed in responding to their infants' cries, the more crying the infants did in later months. Babies whose mothers responded promptly in the first 6 months of life cried less often in the second 6 months. The results of this early research have been supported in many studies of parent–infant interactions. Infants learn to cope with the demands and variations of adult/family interactions, and adults provide the socialization environment that helps to support an infant's emotional appraisals and self-control (Thompson, 2014).

Coordination, Mismatch, and Repair of Interactions

The study of mutuality with the caregiver has focused in some detail on patterns and rhythms of social interaction, especially coordination between the infant and caregivers (Tronick, 2003). Infants are striving to make meaning of their social situation. They do not have language, so they use all the sensory, motor and cognitive resources available to gather information about how to behave, how to sustain and end interactions, and how to get what they need. For example, infants use social referencing to decide if they should approach or avoid an object or another person (Stenberg, 2013).

Infants form expectations for social interactions based in part on their observations of contingencies. They come to recognize that the behavior of one participant in an interaction is predictable based on the behavior of the other. Eventually these observations of contingent interactions become integrated into coordinated patterns of mutuality. For example, in a study of mother–infant vocal interactions, from 4 to 10 months of age, vocalizations became increasingly coordinated. At 4 months, infants were most likely to vocalize at the same time as their mothers vocalized, not when the mothers paused in their vocalizations. In contrast, mothers were more likely to vocalize when the infants were silent, demonstrating the more typical pattern of turn-taking in conversation. However, over time, there were fewer instances of co-vocalization by the infants, and more instances of turn-taking. This research indicates a period of continued development from 4 months and beyond when coordination in vocal interactions will likely show additional evidence of mutual co-regulation (Harder Lange, Hansen, Vǣver, & Køppe, 2015).

Adult caregivers are also learning to read their infant's signals and to provide appropriate care. Some caregivers are better at this than others. Depressed mothers, for example, have been shown to be less expressive and less responsive to their babies than nondepressed mothers (Field, Diego, & Hernandez-Reif, 2009). In the context of thousands of small daily interactions, it is common that the intentions and meanings of the partners are at odds—the infant shifts his or her attention, the caregiver misinterprets the infant's signals, the interaction lasts too long or is over too quickly. These early interactions are often recognized as being mismatched, and there is some attempt at repair. The work of creating mutuality of communication is characterized as a process of coordination, mismatch, and repair (Tronick & Beeghly, 2011).

Coordination refers to two related characteristics of interaction: matching and synchrony. **Matching** means that the infant and the caregiver are involved in similar behaviors or states at the same time. They may be playing together with an object, cooing and smiling at each other, or fussing and angry at each other. **Synchrony** means that the infant and caregiver move fluidly from one state to the next. When infants are paying attention to their caregivers, the caregivers attempt to stimulate them. As babies withdraw attention, the caregivers learn to reduce stimulation and wait until the infants are ready to engage again. Normally, caregiver–infant interactions are typically mismatched (Tronick, 2009). In fact, matched interactions appear to become mismatched rather quickly. Babies are developing rapidly. Their efforts to understand their situation and their changing sensory, emotional, cognitive, and motor abilities all work to bring new intentions and new meaning to social interactions. Caregivers' past experiences in trying to meet their infants' needs do not always adequately inform how to meet the new, changing nature of their infant's behaviors. However, periods of **mismatch** are usually followed by **communication repairs**, As a result, it is not surprising that infants and caregivers continue to experience this "dance" of coordination, mismatch, and repair.

Why is caregiver–infant communication so frequently disrupted? The explanation may lie partly in the infant's inability to sustain coordinated attention with the caregiver, partly in a rapid shift of need states, and partly in the inability of adults to sustain long periods of nonverbal communication. The moments of coordination become a prototype for the positive feelings of connection that people enjoy in social relationships. Long before infants can use language to convey their feelings or needs, they experience the satisfaction of social connection through these cycles of communication. As a caregiver and baby move into renewed moments of coordination, their sense of pleasure increases, leaving a memory of such moments to guide future conversations (Goleman, 2006). Moments of **repair** that follow mismatch are also evidence that interactions that were not well coordinated can be rectified. This leads to hopefulness about the potential in future interactions and persistence even in the face of interactions that seem to veer off course.

At a biological level, what appears to occur through experiences of coordination, mismatch, and repair is the establishment of a neurochemical pattern: Networks of synapses are established; oxytocin is released; pleasurable feelings ensue; and the amygdala is impacted, resulting in reduced arousal and a greater sense of calm. Over time, as a product of experiences of receiving sustained, sensitive caregiving, the infant's complex neurological social capacity for trust is strengthened. Even though the brain is prewired to recognize and respond to certain types of social stimulation, actual caregiving experiences establish more or less likely patterns of social engagement. Infants who experience disrupted, harsh, withdrawn, or neglectful care do not develop the same underlying neurochemical structures for patterns of social behavior as do babies whose caregivers are psychologically available and warm. As they grow older, these children may experience a wide range of problems in social behavior, emotional development, and cognitive development, especially in areas of language and communication competence.

Establishing a Functional Rhythm in the Family

The match or mismatch between an infant's rhythms and the family's rhythms is an important factor in the overall adjustment of a family to a new baby. Some babies are quite predictable; the timing of their sleeping, eating, playtime, and even fussy periods follows a clear pattern. Other babies are much less regular. All babies are changing rapidly during the first 24 months of life, so daily patterns are bound to change, and families must make frequent adjustments in order to continue to meet the infant's needs.

In American culture, by the end of the first year of life, babies are typically expected to modify their schedule of needs so that they sleep when the rest of the family sleeps, play when the rest of the family is awake, and eat three or at most four times a day, generally when the other family members eat. During the second year of life, the demands of parenting change. Babies become more mobile and have new capacities to initiate activities. Their attention span increases, they have new requirements for stimulation, and they have new areas of wariness and resistance—things they don't want to do (like take a nap) or people they don't want to be with (like a certain babysitter). These and other changes require adaptation on the part of parents in order to sustain the mutuality that has been achieved or to rectify problems in attachment and trust that may now be evident. The stable features in mutual relationships are the caregiver's effort to be responsive to the child's changing capacities and needs, and the child's ongoing monitoring of and responsiveness to the caregiver's cues.

Parents with Psychological Problems

The importance of reciprocal interactions in building trust and hope during infancy is highlighted by studies of parents with psychological problems. Sensitivity to an infant's emotional states, the ability to respond appropriately to an infant's needs, and the quality of common, daily interactions can all be impaired by family risk factors. As an example, research has compared interactions between depressed and nondepressed mothers and their infants. Interactions between the depressed mothers and their infants appear to be stressful and mutually unsatisfying (Field, Hernandez-Reif, & Diego, 2006). Depressed mothers have been observed to be unresponsive, emotionally unavailable, and unable to sustain smooth communication with their babies. Compared with nondepressed mothers and their infants, depressed mothers have fewer positive matched states with their babies, and it takes them longer to repair those mismatched states (Reck et al., 2011). Depressed mothers are less likely to show animated, positive facial expressions. Typical efforts at fostering an infant's emotional regulation, commonly observed in nondepressed mothers—such as introducing stimulating toys and games, touching and talking, and the efforts at reducing arousal through appropriate soothing and comforting—are not as common in depressed mothers. For their part, the infants of depressed mothers have few expressions of interest, show more sad and angry expressions, show less ability to match a happy face with a happy vocal expression, and are less able to regulate their emotions (Bornstein, Arteberry, Mash, & Manian, 2011).

The Prime Adaptive Ego Quality and the Core Pathology

Hope

Erikson (1982) theorized that the positive resolution of the psychosocial crisis of trust versus mistrust leads to the adaptive ego quality of **hope**. As you will recall from chapter 3, the prime adaptive ego qualities shape a person's outlook on life in the direction of greater openness to experience and information, greater capacity to identify a variety of pathways to achieve one's goals, more willingness to assert the self and to express one's wishes and views, and a positive approach to the formation of close relationships. Even in the face of difficulties and stressful life events, these qualities contribute to higher levels of functioning and well-being.

As the first of the prime adaptive ego qualities, hope pervades the entire life story. It is a global cognitive orientation that one's goals and dreams can be attained and that events will turn out for the best. As Erikson described it, "Hope bestows on the anticipated future a sense of leeway inviting expectant leaps, either in preparatory imagination or in small initiating actions. And such daring must count on basic trust in the sense of a trustfulness that must be, literally and figuratively, nourished by maternal care and—when endangered by all-too-desperate discomfort—must be restored by competent consolation" (1982, p. 60).

Hopefulness combines the ability to think of one or more paths to achieve a goal with a belief in one's ability to move along that pathway toward the goal (Snyder, Cheavens, & Sympson, 1997). The roots of hopefulness lie in the infant's understanding of the self as a causal agent. Each time a baby takes an action to achieve an outcome, the sense of hope grows. When babies encounter obstacles or barriers to their goals, sensitive caregivers find ways to remove the obstacles or lead them along a new path toward the goal. The infant's sense of the self as a causal agent combined with the caregiver's sensitivity create the context for the emergence of hope.

Research with adults shows that people who have a hopeful, optimistic outlook about the future have different achievement beliefs and emotional reactions in response to actual achievement than do people who have a pessimistic outlook (Seligman, 2011). People who have higher levels of hopefulness undertake a larger number of goals across life areas and select tasks that are more difficult thus leading to higher overall levels of performance (Snyder, 2002). Hopefulness is essential for behavior change in that it combines a desire to achieve new goals and a belief that one will be able to find successful paths toward those goals. Feelings of hope help people deal with difficult challenges, including coping with their own serious injury or illness, parenting children with developmental disabilities, or facing the end of life (Einav, Levi, & Margalit, 2012; Sullivan, 2003).

Within the psychosocial framework, hope provides the platform from which very young children take certain leaps of faith. When an infant overcomes doubts and hesitancy in taking a first independent step, you see the dividend of hope. When a toddler clambers over the bars of her crib and drops several inches to the floor, you see the dividend of hope. As a parent, when you give your adolescent the keys to the car, you see the dividend of hope. Without hope, neither the individual nor the society could bear the weight of uncertainty in our changing world. With hope, individuals can envision a better society and come together in actions to reach the collective good (Braithwaite, 2004).

Withdrawal

As a core pathology, **withdrawal** refers to a general orientation of wariness toward people and objects. This is especially disturbing because, during infancy, healthy development is a pattern of outward motion, extension, and increasing engagement with the social and physical worlds. Infants typically reach and grasp, crawl, stand, and walk. They explore through gazing, mouthing, and manipulating objects. Their behavior is typically characterized by interest in novelty, joy in learning, and frustration at encountering barriers to goal achievement. Over the first year, babies become increasingly connected to significant figures in their social world, following them about, devising strategies to engage them in interaction, and looking to them for consolation when they are distressed.

Infants who are characterized by withdrawal may show evidence of passivity, lethargy, and neutral or negative affect. They are not readily engaged in social interaction and do not show the signs of self-directed exploration that are typical of most healthy infants. Withdrawal may have some of its roots in genetically determined temperamental characteristics. Some babies have a very low threshold for pain. They are highly sensitive to sensory stimulation and recoil from the kinds of handling that other babies find comforting or pleasurable. Some babies are more passive than others, requiring little in the way of stimulation and showing less evidence of exploratory behavior than active babies.

One of the earliest descriptions of withdrawal in infancy was provided by Rene Spitz's (1945, 1946) analysis of children who had been institutionalized before 1 year of age. The babies who suffered the most had been placed in a foundling home in which eight babies were cared for by one nurse. These babies went through a phase of initial rage, followed by a period of physical and emotional withdrawal. They lay passively in their cribs, showing limited motor exploration and little emotionality. Furthermore, they rarely smiled or showed excitement. The babies' babbling and language were extremely delayed. They deteriorated physically. Their measured developmental level dropped substantially over a year's time. These babies suffered from a combination of a loss of their attachment figure, a lack of meaningful social interaction, and an absence of appropriate sensory stimulation—all of which produced what Spitz called *anaclitic depression*.

Not all instances of withdrawal are as severe as the anaclitic depression syndrome. However, a growing literature focuses on the links between disrupted mother–infant interaction, violent parental interactions, and infant social withdrawal (Crockenberg, Leerkes, & Kekka, 2007; Gerhold et al., 2002). Temperamental factors including behavioral inhibition and a low threshold for sensory stimulation, an anxious-avoidant attachment, and a lack of contingent, responsive caregiving can combine to produce mistrust and the formation of the core pathology of withdrawal. Social withdrawal can become such a severe social deficit that it interferes with adaptive functioning and requires clinical treatment (Calkins & Fox, 2002).

FURTHER REFLECTION: *Explain the connection between trust and hope; between mistrust and withdrawal. How are these concepts related?*

How might the sense of trust and the ego strength of hope play a role in the enactment of later life roles such as friend, teacher, supervisor, parent, or political leader?

Applied Topic: The Role of Parents

OBJECTIVE 8 Evaluate the critical role of parents and caregivers during infancy, with special attention to issues of safety and nutrition; optimizing cognitive, social, and emotional development; and the role of parents and caregivers as advocates for their infants.

In this chapter, we have portrayed infants as active, adaptive, and eager to master the environment. At the same time, the immaturity of human infants at birth necessitates a long period of dependence on adults. The few instinctive behaviors of human infants in comparison with the infants of other species are compensated for by their enormous capacity to learn. For this potential to be realized, infants must rely on their parents to maintain their health, provide stimulation, and protect them from danger. During the period of dependence, infants become entwined in complex social systems and develop strong emotional bonds with their caregivers. The quality of these early relationships provides infants with mental representations that guide their later development of friendships, intimacy, and relationships with their own children.

Infancy, just like pregnancy and childbirth, is culturally constructed. The content of experience and the way the period of infancy is viewed depend on cultural traditions, beliefs, and technologies. Some of the ways that culture defines infancy include the infant's sleeping arrangements, the choice of clothing, the choice of the infant's name and the naming process, the selection of foods, and access to nursing from mothers and other lactating women. Parents transmit the culture through their care, and by enacting certain rituals and practices, they introduce and integrate their infant into the cultural community.

Oliver Benn/The Image Bank/Getty Images

Infancy is culturally constructed. Cora rises early each morning, ties her infant to her back, and walks to the market to sell flowers. She expects her baby to be calm and quiet while she earns her living.

The **Human Development and Diversity** box Sensitive Care in Two Cultures provides a contrast between features of sensitive care for U.S. mothers and Colombian mothers.

Five aspects of the parental role promote optimal development in infancy: ensuring safety and providing adequate nutrition; fostering socioemotional and cognitive development; coordinating the roles of father and mother; acting as **advocates** with other societal systems; and connecting with other sources of social support.

Safety and Nutrition

Safety

One of the central responsibilities parents face is to protect infants from environmental dangers. The nature of home and neighborhood influences the kinds of dangers to which infants are exposed and the kinds of practices that families and cultures invent to protect their children. In addition to physical risks, some dangers are linked to superstitions, religious beliefs, and matters of the spirit world. In many parts of the world, parents take special precautions to prevent their infants from coming under the influence of an evil eye. The eye gaze may be viewed as a vehicle through which a person may deliberately or inadvertently transmit harmful feelings of jealousy, revenge, or unbridled pride (Galt, 1991). The presence of dangers or risks in the environment usually elicits some effort to restrict a child's movement. Swaddling, carrying the baby in a sling, or placing the baby in a playpen are examples. Because of concern about dangers, caregivers may invoke certain prohibitions, such as telling the child, "No, don't touch that," or pulling the child away from something dangerous. As infants become more mobile in the second half of their first year, the need to monitor and limit exploratory activities increases. Depending on the cultural values concerning independent exploration, caregivers may heighten their restrictions and prohibitions or they may try to modify the environment to permit safe, unrestricted exploration.

Certain childrearing practices arise from a desire to protect young children from known dangers. For example, Robert LeVine (1977) described the practice of many African cultures of carrying infants 18 months and older on the back, even though they were able to walk around. This practice was used to prevent toddlers from getting burned on the open cooking fires at an age when they were mobile enough to walk or stumble into the fire and yet not old enough to know how to inhibit their movements. Other hazards, such as falling off steep cliffs or into lakes, rivers, or wells, prompted this same carrying behavior.

In industrialized countries, infants may face different types of hazards, such as electrical outlets, steep stairs, and open containers of insecticides, cleaning agents, and other poisons. Lead is a known neurotoxin. Lead poisoning has an especially negative impact on infants and young children, resulting in life-long cognitive and behavioral impairments. Lead can leach into drinking water from lead-based plumbing and contaminated water sources, a condition that is particularly dangerous for infants whose formula is made with water from the tap (Hanna-Attisha, LaCance, Sadler, & Schnepp, 2016).

Some families protect babies from danger by putting gates at a doorway or the top of a stairway, or by placing an infant in a crib or playpen to restrict exploration. In other homes, the strategy is to *baby proof* the home by

Sensitive Care in Two Cultures

Socialization toward culturally valued goals is a primary focus of parenting. This socialization process begins in infancy and is expressed through the beliefs parents have about what children should be able to do and what they should know or understand in the period of infancy. These beliefs are translated into caregiving strategies (Lamm & Keller, 2007). A primary assumption of attachment theory is that the quality of early care, and especially sensitive caregiving, promotes attachment security, an assumption that has been supported in a large number of studies (De Wolff & van IJzendoorn, 1997). However, the behavioral components of sensitive caregiving and how it might be expressed in various cultures has not been explored in great detail. A study by German Posada and colleagues (2002), which contrasted maternal care in two middle-class samples, one in Denver, Colorado, and the other in Bogota, Colombia, was designed to clarify this topic.

Although men's and women's roles are changing in Latin America, especially among the urban middle class, the Colombian culture is considered more collectivistic and interdependent than the U.S. culture, which is viewed as more individualistic and independent. Two questions guided the research: (1) Are the features outlined in the attachment literature that define sensitive care descriptive of care in both cultures? (2) Are there features of care that might be unique to the specific cultures that are related to attachment security?

The researchers used an ethnographic methodology to formulate categories of maternal behaviors. Two researchers observed mother–infant pairs at home for two 2-hour visits. Following the visits, the observers used a Q-sort technique to describe the mothers' behaviors. This technique involved sorting 90 cards that describe maternal behavior into three piles: characteristic, neither characteristic nor uncharacteristic, and uncharacteristic. Each of the three piles is then further sorted into categories rated from 1 (most uncharacteristic) to 9 (most characteristic).

From this rating process, eight categories of care were identified. Four of these categories were very similar to features of sensitive care outlined in the basic attachment research: (1) sensitive responding to infant signals and communication; (2) accessibility, which reflects a mother's ability to consider the baby's needs despite other competing demands; (3) acceptance of the infant, which is reflected in the mother's positive emotional tone when interacting with the baby; and (4) interference, a mother's intrusive or non-coordinated interactions with the baby. Two categories were observed that had not been captured in the literature as related to sensitive care: active, energetic interactions with the baby and creating an interesting environment for the baby. One category was observed in each cultural group that was unique to that culture: For the U.S. mothers it was close-intimate interactions involving cuddling and close affectionate touching; for the Colombian mothers it was concern with the baby's physical appearance, including concern that the baby was getting messy during feeding and that the baby was messy or soiled during play.

Mothers from the United States and Colombia were very similar in their scores on sensitive responding, accessibility, and acceptance, and all these dimensions were predictive of infants' secure attachments. Mothers from Colombia were less interfering and more active and energetic in their interactions than the U.S. mothers. Mothers from the United States scored higher on creating an interesting environment for the baby. Of these three dimensions, interfering was negatively related to secure attachments for the U.S. sample, but not for the Colombian sample, and being active and energetic was positively related to secure attachment for the Colombian sample but not for the U.S. sample.

The results of this study highlight several points about the role of parents during infancy. First, certain features of parenting appear to have beneficial consequences for infants in both cultures. When combined with results from many other studies, these features are becoming accepted as universally supportive of the attachment process—attuned response to the

Vasiliy Koval/Shutterstock.com

It is typical for mothers in the United States to create a stimulating environment for their babies by providing lots of toys and other interesting objects for exploration and play.

infant's signals, accessibility in the face of competing demands, and acceptance or the positive emotional tone of mother–infant interactions. Second, some features of parenting are observed across cultures but not always related to attachment security in every culture. Third, some features of parenting may be culturally or contextually specific and, while important for early socialization, may not be specifically relevant for the formation of a secure attachment.

Critical Thinking Questions

1. Based on this study, list the basic features that are essential for sensitive caregiving across both cultures.
2. Evaluate whether the differences in caregiving between the U.S. and Colombian samples fit with characterizations of these cultures as more individualistic or collectivistic.
3. The research has captured a few features of caregiving that are distinct between the U.S. and Colombian cultures. Discuss the implications of these differences for infant socialization and subsequent socialization.
4. Evaluate the strengths and weaknesses of the Q-sort methodology for assessing features of the caregiving environment. Design another approach that might be used to capture cultural differences in caregiving.

removing as many known dangers as possible so that the baby has maximum freedom for exploration. These two different strategies reflect different values concerning childrearing—both with the same goal of providing maximum safety and protection from danger. In the former, parents try to preserve their adult environment. Children must modify their behavior in order to fit into the home. In the latter, parents modify the environment to accommodate the baby's developmental needs. For more information about child safety, you may want to visit the website of the U.S. Consumer Product Safety Commission section on safety for kids and babies. This agency publishes reports on recalls, statistics on injuries and deaths, as well as guidelines for child safety and toy safety.

Nutrition

In addition to protecting children from dangers and preventing injuries, parents are responsible for providing an age-appropriate diet that supports the infant's changing nutritional needs. An estimated 30 percent of children under the age of 5 in developing countries suffer from malnutrition, which is known to result in stunted growth as well as disruptions in brain structures associated with cognitive and behavioral development (Venables & Raine, 2016). Infant nutrition and health are significantly associated with childhood and adult intelligence (Kanazawa, 2015).

The American Academic of Pediatrics recommends exclusive breastfeeding for the first 6 months of life (American Academy of Pediatrics, 2012; 2016). Human milk is sufficient to provide the baby's nutritional needs. In addition, breastfeeding is associated with many health benefits including reduced risk of ear infections, fewer respiratory infections, fewer infections that inflame the intestines, lower risk of chronic diseases such as asthma and diabetes, reduced risk of childhood obesity, and lower risk of sudden infant death syndrome. Newborns may nurse every 2 to 4 hours; by 4 months of age, babies may nurse 4 to 6 times in 24 hours. If the baby is breastfeeding, mothers have to be careful about how their own diet and medications might affect their breast milk. If they are using formula, they have to be careful about the water quality that is used. In some areas of the world, poor water quality makes the use of powdered formula a serious health risk for infants.

The transition to solid foods, sometime around 4 to 6 months, leads to both safety and dietary concerns. Babies need to be strong enough to hold their heads up and to sit with some support so they do not choke on solid foods. Typically, parents are instructed to introduce some type of iron-fortified rice cereal mixed with breast milk or formula as the first solid food. New foods are introduced one at a time, giving the baby a few days to become accustomed to the new taste, watching for signs that the baby is able to digest the new food, and also ensuring that the baby is not allergic to the food. Most resources on pediatric nutrition advise against giving infants honey, which can cause botulism.

Safety concerns related to food include: avoid foods that are likely to cause choking like nuts, raisins, or large pieces of meat; avoid giving bottles with milk, juice, or sweetened beverages, which can cause tooth decay, at bedtime; avoid feeding the baby from the jar in order to prevent bacteria from the baby's saliva from contaminating unused portions of the food; and avoid keeping opened jars of baby food (Foodsafety.gov, 2016).

Many first-time parents are unsure about how to provide adequate, safe nutrition for their babies. This is a source of some anxiety because it is an area in which the infant so obviously depends on caring adults for health, safety, and survival. Many excellent resources are available to inform parents about infant nutrition, including online resources such as the Mayo Clinic and the MedLine Plus of the National Institutes of Health. The WIC (Women, Infants, and Children) program provides federal grants to states to make supplemental foods, health care referrals, and nutrition education available for low-income pregnant, breastfeeding, and non-breastfeeding postpartum women, and to infants and children up to age 5 who are found to be at nutritional risk (USDA, 2016).

Fostering Socioemotional and Cognitive Development

Another component of the parents' role during infancy is the promotion of socioemotional and cognitive development. Much of the behavior that appears to be important in the development of strong emotional bonds between infants and parents is also central to fostering intellectual growth. Three features of parenting quality have been found to support optimal development, including children's language, literacy, cognition, autonomy, self-efficacy, and school readiness. They are (1) parenting sensitivity, (2) cognitive stimulation, and (3) warmth (Lugo-Gil & Tamis-LeMonda, 2008). As was discussed earlier, parenting sensitivity refers to the way parents respond to their infant's distress, emotional expressions, interests, and abilities, effectively balancing the infant's needs for comfort and reassurance with the infant's needs for autonomy and self-control. Cognitive stimulation refers to parents' efforts to teach their child, to enrich the child's language and cognitive development, and to provide an interesting, age-appropriate environment. Warmth refers to the parents' expressions of affection, admiration, and respect for their child.

Parents foster both emotional and intellectual growth by structuring the stimulus environment to suit the infant's developmental level (Bornstein, 2012). Part of the parents' function is to initiate interactions and not just respond to their infants' demands for attention. Parents need to create what they perceive to be a suitable environment—one that allows a variety of experiences, a reasonable amount of challenge, and adequate opportunities to experience success. Furthermore, parents should be attuned to their infant's developing skills and alter the environment appropriately. As their children mature, parents must provide more complex stimuli, more opportunities for autonomy, and more encouragement for tolerating frustration. By providing experiences that are attuned to the infant's level of cognitive functioning, parents are also supporting emotional satisfaction, confidence, and joy.

Parents use a variety of methods to help their infants regulate their emotions. Through physical and verbal play, they increase the baby's arousal and orient the baby toward objects in the environment. Through soothing and comforting, they help their infants regain a calm state after distress. As babies mature, parents increase their use of language to guide behavior and provide new problem-solving strategies. Infants are constantly watching their parents, observing their emotional reactions as well as their novel behaviors. As a negative example, we have discussed how infants of depressed mothers become passive and inhibited in their reactions to the environment as they observe their mothers' passive or angry depressive symptoms. Another example is the influence of harsh parenting or maltreatment on infants' emotional negativity, especially fearfulness and anxiety, and problems in emotional regulation.

U.S. parents of infants have made enormous expenditures for special toys, music, videos, and infant stimulation programs intended to foster intellectual development. A desire to provide resources to promote infant stimulation in the period from birth to 3 years of age in order to ensure optimal cognitive growth is probably important. However, in their desire to support optimal development, parents need to be wary of fads and hypes that make it seem as if some specific form of stimulation is essential for their baby's growth. In an international study of caregiving practices, Bornstein and colleagues identified six basic caregiving practices that are associated with optimal psychosocial development in the first 12 months of infancy: read books to the baby; tell the baby stories; name objects, count, and/or draw with the baby; play with the baby; sing songs with the baby; and take the baby outside (Bornstein, Putnick, Lansford, Deater-Deckard, & Bradley, 2015). These practices, which are observed in a range of 38 low- and middle-income countries, highlight the value of face-to-face processes that promote infant attention, emphasize a positive emotional tone, and engage the infant in the objects and resources of their near environment.

Parents and other sensitive caregivers are the most valuable sensory and emotional assets a baby can have. Rhythmic interactions, positive tone, comfort and soothing care under conditions of distress, and playful, relaxed interactions that allow babies to initiate as well as to follow are among the most valuable forms of stimulation for promoting social, emotional, and cognitive growth in infancy.

Fathers' and Mothers' Parental Behaviors

Do fathers and mothers differ in how they enact the parent role with infants? Babies form strong attachments to their fathers as well as to their mothers. Fathers may be just as involved in and sensitive to their babies' needs as mothers. However, the daily interactions between mothers and their babies and those between fathers and their babies are distinct. In a national time use survey, mothers and fathers who had children under the age of 6 were compared, based on their employment status (Table 5.9). Regardless of their employment status, mothers spend more time each day on the care of their young children than fathers. The

Table 5.9 Average Hours per Day Spent with Children under Age 6 by Mothers and Fathers by Employment Status

	Married Mothers			Married Fathers	
Activity	**Employed Full Time**	**Employed Part Time**	**Not Employed**	**Employed Full Time**	**Not Employed**

Source: Bureau of Labor Statistics (2016). American Time Use Survey, 2009-2013, Table A6.

difference is especially notable in the time spent on physical care, where mothers spend almost twice as much time as fathers (U.S. Bureau of Labor Statistics, 2016). Fathers, who spend less time overall with their babies, tend to focus more on play—especially physical play. They use their strength and physical activity as resources as they interact with their babies. When mothers play with their babies, the play tends to be with words or with toys, as opposed to rough-and-tumble activity (Laflamme et al., 2002).

Cameron, a stay-at-home father of two daughters (an infant and a two-year-old), speaks about how he thinks fathers are different from mothers: “I find I am very playful with the girls. I become the play structure you know. I will have them sitting on me. We’ll sing ‘the people on the bus’ and *I’m the bus!* I’m the slide.’ I don’t think I’ve ever really seen my wife do that. I will do it for hours at a time throughout the day. They are climbing all over me all day long” (Doucet, 2009, pp. 86–87).

The experience of parenting results in changes in the brain, particularly neural regions that are associated with parental motivation. Fathers form mental representations of their infants that stabilize from the prenatal period through the first months of an infant’s life. When presented with images of their young infants, a network of brain regions are activated, accompanied by the release of hormones that are associated with parental sensitivity and reciprocity (Kim et al., 2014; Kuo, Carp, Light, & Grewen, 2012; Vreeswijk et al., 2014).

Both fathers and mothers have strategies for soothing their infants. However, the quality of interaction between fathers and infants depends on the context. When mothers are present, for example, fathers interact less with their babies. When fathers are alone with their babies, they are more engaged and sensitive play companions. Men who are not overly stressed at work, have strong positive identification with their own fathers, and are in satisfying, harmonious marriages, achieve greater levels of intersubjectivity with their babies. Fathers who are in relationships that they describe as very satisfying are also observed to engage in more responsive, sensitive interactions with their infants (Barnett, Deng, Mills-Koonce, Willoughby, & Cox, 2008). What is more, when fathers are actively engaged in parenting, their involvement contributes to a mother’s confidence. Women whose husbands share in the care and comfort of their infants are better able to cope with their infants’ distress (Dayton, Walsh, Oh, & Volling, 2015).

Even fathers who are not married to their baby’s mother seem to be involved in the baby’s life in the early months after birth. Many of these fathers, especially those who are cohabiting or are romantically involved with the mother but live apart from her, provide direct and indirect support, want their name on the child’s birth certificate, and say they want to help in the child’s care. Unfortunately, this level of involvement often does not persist into the child’s toddlerhood or early childhood. As the relationship between the parents dissolves, the father’s involvement with his child also diminishes. By the time the child is 5 years old, only half of the non-resident fathers had seen their child in the past month (Fragile Families and Child Welfare Study, 2016).

Despite the gender stereotypes it is clear that fathers can be gentle and soothing with their infants, and mothers can enjoy moments of silly tickling and play.

The quality of the relationship between the parents is vital for an infant's well-being. When adults are in constant conflict or when there is physical violence, loud yelling, or emotional abuse between the partners, infants suffer. In these families, infants may be at risk for direct abuse and/or neglect, but they may also be at risk simply through exposure to inter-parental aggression. As a result, infants may experience anxiety, disruption of executive functions, and problems with emotional regulation, which are associated with a range of mental health problems. The link between parental dysfunction and child outcomes will be explored further in subsequent chapters.

Parents as Advocates

In addition to providing care themselves, more and more parents are responsible for arranging supplemental care for their infants. As a result, parents become advocates for their child. Parents must review the child care services available to them and select a setting that will meet their infant's needs and accommodate their work requirements and economic resources. Family day care, in-home babysitting, and center-based care are three common alternatives.

To function as advocates for their children, parents may have to engage in an unfamiliar kind of thinking. They may even feel unqualified to make the kinds of judgments required. For example, parents must evaluate the competence and motivation of the adults who will care for their child. They must estimate how successful these caregivers will be in meeting their child's needs for security and stimulation. And they must consider the degree to which alternative caregivers reflect their own parental values, beliefs, and strategies.

Even when pressures to continue a caregiving arrangement are very strong, parents must be able to assess its impact on their children. They must judge whether their children are in the kind of responsive, stimulating environment that will enhance their development. In the best situations, alternative care settings actually complement a parent–infant relationship. In the worst settings, infants may be neglected and abused. It is essential for parents to maintain communication with the alternative caregivers, assess the quality of the care, and intervene promptly when necessary to ensure their infant's well-being.

Another situation in which parents serve as advocates for their infants occurs when the children have some form of chronic illness, developmental delay, or disability. These children may require coordinated health care, therapeutic interventions, mental health services, and educational supports. The Individuals with Disabilities Education Act (IDEA) requires every state to provide early intervention programs to support parents and help them understand the nature, prognosis, and treatment of the infant's condition from birth through age 2. Although each state has some discretion in the way they implement early intervention services, the program typically assigns case managers to families to help connect parents and infants with physicians and other health professionals. Case managers may also provide home services, identify the least restrictive environments for infants who need care, and assist in the identification of appropriate community resources (U.S. Department of Education, 2016). However, parents are ultimately responsible for making sure that the services match the child's changing needs.

The Importance of Social Support

The infant's physical, cognitive, social, and emotional development are fostered through the loving care of mothers, fathers, other family members, and community caregivers who are able to create supportive relationships with one another and with the infant. Infant mental health and optimal development are intimately entwined with the mental health of caregivers (Fay-Tammbach, Hawes, & Meredith, 2014; Karevold, Røysamb, Ystrom, & Kristin, 2009; Weatherston, 2001). A variety of factors play a part in parents' ability to promote their child's optimal development. Adults who had difficult experiences with their own caregivers may come to the parental role with special challenges. They may not have experienced the comfort, responsiveness, or appropriate stimulation that are essential for effective parenting. Some factors, however, help to make up for these deficits. The quality of one's intimate relationship with a loving partner is important in sustaining positive parent–child relationships. Couples who experience mutuality and trust in their own relationship are better able to create a predictable, supportive, and caring family environment for their children (Crockenberg, Leerkes, & Lekka, 2007).

Sources of **social support** beyond the intimate partner may also enhance one's effectiveness as a parent. This support may come from the child's grandparents and other family members, friends, and health care and mental health professionals (Bornstein & Tamis-LeMonda, 2010). Both men and women can benefit from talking with their friends about how to care for their infants. This seems to be easier for women to do than for men, but when men are able to talk freely with other men about their father role, it provides tremendous reassurance and can enhance their sense of parental efficacy (Bagnini, 2014).

The effective use of a social support network ensures that adults will not be isolated as parents, and that others will be available to help the parents identify and interpret childrearing problems. Often, the help is very direct—for example, child care or sharing of clothes, playthings, and furniture. Support may also take the form of companionship and validation of the importance of the parental role. However, social support cannot fully compensate for the lack of partner support or for the stresses on parenting caused by economic pressures that prevent parents from meeting basic life needs.

In reviewing this chapter, you can begin to appreciate the demanding nature of the parental role in promoting optimal development during infancy. The elements of effective parenting that we have identified or implied are listed in Table 5.10. As a parent, one must rely heavily on one's own psychological well-being and on the encouragement of one's spouse, caring friends, and family to sustain the ego strengths and emotional resources necessary to the task.

The way parents conceive of their role has a major influence on the direction and rate of their infants' development. Parenting also allows adults opportunities for creative problem solving,

Table 5.10 Optimizing an Infant's Development

Spend time with the child; be available when the child needs you.
Provide warmth and affection; express positive feelings toward the baby in many ways—verbally, through touching and hugging, and through playful interactions.
Play with the baby; sing songs; make up little games.
Communicate often, directly with the child; engage the child in verbal interaction.
Read to the baby; tell the baby stories.
Provide stimulation.
Encourage the child's active engagement in and exploration of the indoor and outdoor environments.
Help the child understand that he or she causes things to happen.
Help the child engage in directed problem solving. Encourage the child to persist in efforts to reach a goal.
Keep things predictable, especially when the infant is very young.
Guide language development by using words to name, sort, and categorize objects and events.
Accept the child's efforts to achieve closeness.
Be sensitive to the child's state; learn to interpret the child's signals accurately; time your responses appropriately.
Find effective ways to soothe and comfort the child in times of distress.
Help the child interpret sources of distress and find ways to regulate distress. Minimize the child's exposure to intensely negative, hostile, and frightening events.
Be aware of the visual and auditory cues you send when you interact with the child.
Pay attention to how the child is changing over time.
Monitor the child's emotional expressions to evaluate the success of specific actions and interventions.

© Cengage

empathy, physical closeness, and self-insight. Enacting the parent role makes considerable physical, cognitive, and emotional demands, but attachment to a child also promotes the parent's own psychosocial development. These contributions to adult development are described further in chapters 11 (Early Adulthood) and 12 (Middle Adulthood).

FURTHER REFLECTION: *Hypothesize how life conditions such as poverty, the dual-earner family, single parenting, or having a very-low-birth-weight baby might influence a person's ability to function as an advocate for his or her infant.*

Summarize how infants may influence and even enhance the lives of their family members.

CHAPTER SUMMARY

The genetic plan plays a major role in guiding physical and sensory/perceptual maturation during infancy. There is also considerable evidence for plasticity in neurological development as an infant interacts with the social and physical environments. During infancy, a child rapidly develops sensory and motor skills, social relationships, and emotional and conceptual skills. Babies are born with the capacity to perceive their environment and to evoke responses from their caregivers. They are ready to respond to a wide array of caregiving conditions. Caregivers convey cultural beliefs and values through their childrearing practices, thereby shaping the infant's experiences along particular cultural pathways. The result is a blend of many universal features of infancy, such as reflexes, motor development, attachment processes, and sensorimotor reasoning, with the specific experiences infants have in their culture of care. Some of these experiences are a result of socialization goals, such as sleeping arrangements or types of food that are given to the infant. Some of the experiences are a result of the language, communication patterns, and social interactions that accompany care. Other experiences are a result of individual differences in the caregivers' sensitivity and ability to meet infants' needs.

OBJECTIVE 1 Describe characteristics of newborns and explain the challenges facing low-birth-weight babies.

Babies differ in their physical maturity and appearance at birth. Differences in physical maturity have distinct consequences for the capacity to regulate survival functions such as breathing, digesting, waking, and sleeping. The Apgar scoring method is used to evaluate the newborn's need for immediate intervention. Infants who weigh less than 2,500 grams (about 5 pounds, 8 ounces) are called low-birth-weight babies. Babies who are small for their gestational age (SGA) are at greater risk for health problems than those who are born prematurely but are of average weight for their gestational age. Babies born before 30 weeks do not have the benefit of positive features of the uterine environment that support the maturation of various aspects of self-regulatory functions.

OBJECTIVE 2 Identify important milestones in the maturation of the sensory/perceptual and motor systems. Describe the interactions among these systems during the first 2 years of life. Explain how brain development in infancy is tied to maturation of the sensory and motor systems.

It makes sense to think of infants as newly developing systems that require continuous support for ongoing growth and refinement. The synapses in their brains become more elaborated in the context of engagement in a stimulating and responsive environment. As regions of the brain become more organized, they influence each other, leading to new cognitive capacities and abilities for goal-oriented behavior and self-regulation. The infant brain, including capacities for social connection, sensory processing, motor behavior, and emotional regulation and expression, is emerging in an ongoing, fluid process of exchange of information with its social and physical environments. What begins as an explosion of possible meanings and connections gradually becomes sculpted into certain patterns and preferred responses, but with a continuous potential for new interconnections into childhood and beyond.

During the first months of life, the sensory/perceptual system—vision, hearing, taste, smell, touch, motion sensitivity, and responsiveness to internal cues (*proprioception*)—is developing rapidly and functions at a more advanced level than the motor system. Young infants can distinguish changes in the loudness, pitch, duration, and location of sounds. They can use auditory information to differentiate objects from one another and to track the location of objects. Infants respond to a variety of visual dimensions, including movement, color, brightness, complexity, light-dark contrast, contours, depth, and distance. By 6 or 7 months of age, infants treat faceness as a special visual category. Newborns can differentiate sweet, sour, bitter, and salty tastes. Touch is an active as well as a passive sense; babies use it to explore objects, people, and their own bodies. Over the first year, infants' voluntary motor functions mature rapidly. Many motor functions are present in a reflexive form and emerge more fully as a result of continuing muscle development, motor coordination, and practice. Stepping is one example of this dynamic emergence.

OBJECTIVE 3 Discuss the development of sensorimotor intelligence, including an analysis of how infants process information, organize experiences, conceptualize causality, and understand the properties and functions of objects.

Sensorimotor intelligence begins with the use of motor and sensory/perceptual capacities to explore and understand the environment. Four basic information-processing abilities provide the cognitive resources that support the maturation of sensorimotor intelligence: attention, processing speed, memory, and representational abilities. Of the many schemes that are established during this period, the emergence of an increasingly complex sense of causal relationships, the establishment of the concept of object permanence, and the formation of categories of objects are achievements that impose order and predictability on experience.

OBJECTIVE 4 Summarize the beginnings of language competence from birth through the first 2 years of life.

Evidence of both language perception and language production can be traced to infancy. Auditory and visual cues contribute to an awareness of the structure and rhythm of spoken language. Infants are able to recognize sounds and differentiate between sound combinations. They communicate through babbling and gestures before using spoken words. Around the age of 8 months, infants understand the meanings of some individual words and phrases. By 16 months, an infant has a receptive vocabulary of between 90 and 300 words and a productive vocabulary of about 26 words.

OBJECTIVE 5 Analyze social attachment, the process through which infants develop strong emotional bonds with others, and describe the dynamics of attachment formation during infancy.

A social attachment forms between the infant and the primary caregiver, creating the basic mental representation for subsequent intimate relationships. The attachment has physical as well as social and emotional characteristics. Sensory/perceptual and motor experiences with the caregiver's voice, touch, aroma, facial expressions, soothing, and playfulness are all part of what become integrated into the mental representation of the object of attachment. Depending upon the sensitivity of the caregiver, attachments can be secure, resistant, avoidant, or disorganized.

OBJECTIVE 6 Examine the nature of emotional development, including emotional differentiation, the interpretation of emotions, and emotional regulation. Analyze the concept of temperament as an organized aspect of emotional reactivity.

Emotions are an early and continuous means of achieving intersubjectivity between infants and their caregivers. Emotions become increasingly differentiated in intensity and meaning. Emotional regulation provides a critical underpinning for subsequent cognitive functioning and social competence. Temperament refers to relatively stable ways that infants have of responding to stimulation, regulating their reactions, and engaging objects and people in the environment. Several models or approaches to characterizing temperament are described. A child's temperament influences the tone of interactions, the frequency with which interactions take place, the way others react to the child, and the way the child reacts to the reactions of others.

OBJECTIVE 7 Explain the psychosocial crisis of trust versus mistrust; the central process through which the crisis is resolved, mutuality with the caregiver; the prime adaptive ego quality of hope; and the core pathology of withdrawal.

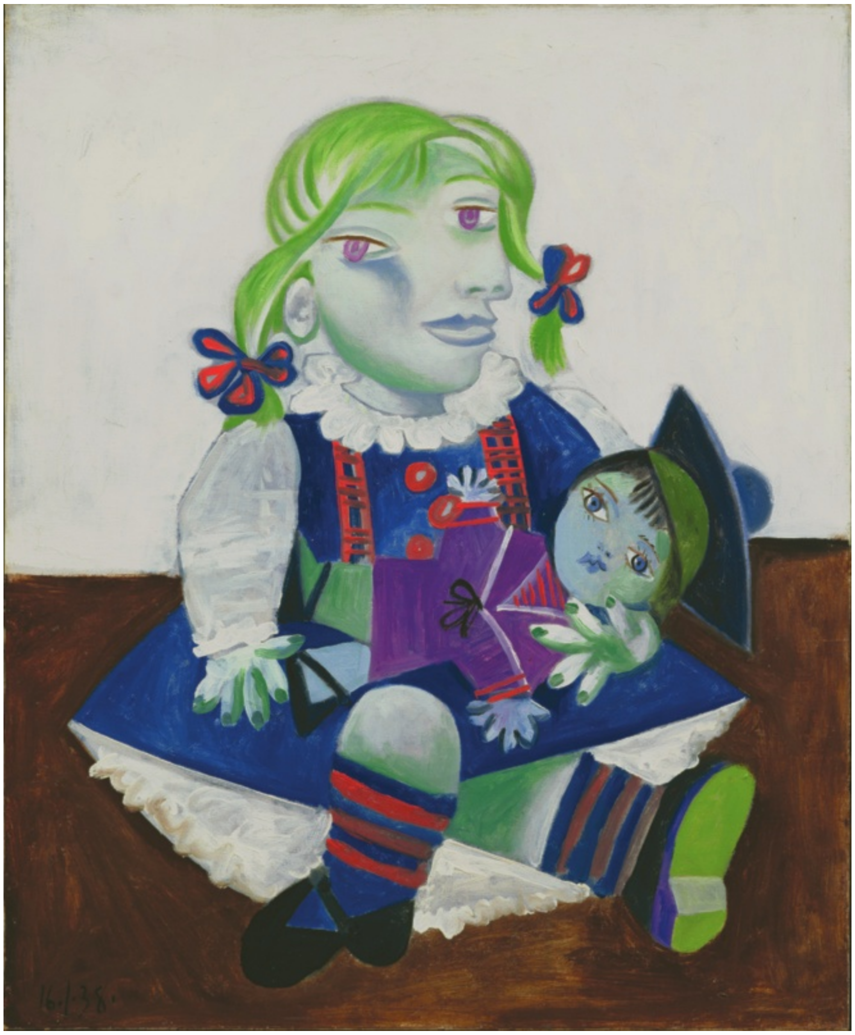
The establishment of trust between the infant and the caregiver is significant in both intellectual and social development. Through repeated interactions with caregivers, the infant develops a concept of the adult as both separate and permanent. Parental sensitivity is an underlying factor in determining the quality of attachment. Factors that appear to influence sensitivity are the adult's past experiences, including how the parent was cared for as a young child; contemporary factors that influence the caregiver's well-being, self-esteem, and emotional availability, such as the quality of the parental dyad and experiences at work; and characteristics of the infant. Once established, the trusting relationship between the infant and the caregiver becomes a source of security for the infant's further explorations of the environment and a framework for future close relationships. Trust serves as a basis for an orientation toward hopefulness.

OBJECTIVE 8 Evaluate the critical role of parents and caregivers during infancy, with special attention to issues of safety and nutrition; optimizing cognitive, social, and emotional development; and the role of parents and caregivers as advocates for their infants.

Infants are skilled at adapting to their environment, but they cannot bring about major changes in it. Parents and other caregivers are ultimately responsible for structuring the environment so that it is maximally suited to the infant. Infants count on their caregivers to create a safe environment, to provide safe and adequate nutrition, to protect them from distress, to promote their health and physical growth, and to rally appropriate social support and community resources as needed. Parents must act as advocates for their infants and for themselves in the parental role.

CASEBOOK

For additional case material related to this chapter, see the case of "Marcie and Mom," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman, pp. 54–55. The case offers a starting point for discussing a common parenting routine—bedtime—and how infant temperament, mother's parenting style, and context interact to create a parenting environment.



Maya with a Doll, 1938 (oil on canvas), Picasso, Pablo (1881-1973)/Musee Picasso, Paris, France/Bridgeman Images

A hallmark of toddlerhood is the emerging capacity for pretense. It begins with the imitation of activities the child has observed at home and evolves into complex fantasy play. Maya can take care of her baby, feed her, soothe her, and put her to sleep. Imagination, language, and physical skills all contribute to the expression of symbolic play.

LEARNING OBJECTIVES

1. Describe the expansion of motor skills during toddlerhood, and explain their importance for the child's capacity to explore the environment and to experience opportunities for mastery.
2. Summarize the accomplishments in language development and outline the features of the language environment that support communicative competence.
3. Explain the development of fantasy play and its importance for cognitive and social development.
4. Examine the factors that contribute to the development of self-control, including impulse management and goal attainment.
5. Define the psychosocial crisis of autonomy versus shame and doubt, the central process of imitation, the prime adaptive ego strength of will, and the core pathology of compulsion.
6. Evaluate the impact of poverty on development in toddlerhood.
7. Apply a psychosocial analysis to the topic of child care, emphasizing the impact of the kind of care and the quality of care on development during toddlerhood.

Chapter Summary

— CASE STUDY Harrison Struggles in the Transition to Preschool —

Harrison was 27 months old when he joined the toddler room. After a few days, Harrison began to have conflicts just after arriving in the morning. He would not wash his hands or come to the breakfast table. When teacher Rena tried to invite him, he worked himself into a rage, yelling the F word (with his own particular pronunciation) and throwing things. Because his behavior distressed the other toddlers, Rena had to physically move him to a far corner of the room, and hold him until he calmed down.

When Harrison repeated this behavior over the following days, Rena talked with Betty, his young mom, whom she had met only a few days earlier. Rena said she enjoyed having Harrison in her group. But, she told Betty, he was having a problem, especially after he arrived, and she wanted to help him.

Betty shared that their house was small, and the activities of some family members often kept Harrison from settling down and getting to sleep. From their conversation, Rena concluded that the toddler's aggressive behavior was due to lack of sleep related to conditions at home.

Over that first month, Rena developed a relationship with Betty, who disclosed a bit more about the family's home situation. Rena learned that two male members of the family were particularly affected by poverty and clinical depression.

Harrison was clearly bringing a high stress level to the toddler room. Rena guessed that the stress was largely due to Harrison's having to transition from one chaotic situation at home to what he perceived as another chaotic situation in the classroom.

Rena worked out a strategy with Betty and the other staff. When Harrison arrived in the morning, she approached him in a low-key way and gave him the choice of getting ready for breakfast or snuggling. Harrison usually chose snuggling and occasionally fell asleep. During the day, Rena gave him choices between two activities. Harrison began making choices and participating more. Rena and the two assistant teachers also sought out opportunities for one-on-one snuggling and contact talks—a few minutes of shared quality time—with him throughout each day.

Gradually, Harrison accepted the toddler routine. Rena remained open to his need for a morning snuggle, but Harrison needed closeness on arrival only some days. The staff realized that while they could not change Harrison's home environment, they could help him feel safe and welcome in the toddler room and maintain a positive relationship with his mother.

CASE ANALYSIS Using What You Know

1. Analyze the features of toddlerhood that are captured in this case. How does the case relate to the developmental tasks of locomotion, language, and self-control?
2. Evaluate Rena's interpretation of Harrison's behavior. What evidence supports the link between lack of sleep, stressful home environment, and a child's aggressive behavior? What alternative interpretations can you think of to explain Harrison's behavior?
3. Explain the relationship of attachment security to a child's ability to cope with stress.
4. How are Rena and the staff using guidance strategies to support Harrison's successful adjustment to toddler care? What might be some long-term benefits of these approaches for Harrison?

Toddlers seem to bubble with unpredictable, startling thoughts and actions that keep adults in a state of puzzled amazement. Toddlers are extremely busy—talking, moving, fantasizing, and planning all the time. Their outpouring of physical activity is remarkable for its vigor, constancy, and complexity. Equally impressive is the flood of cognitive accomplishments, especially language production and unique forms of playful fantasy.

Building on a foundation of trust and optimism formed during infancy, toddlerhood brings a flowering of the sense of personal **autonomy**, an enjoyment and confidence in doing things for oneself and expressing one's will. The successful blending of these two basic capacities for trust and autonomy provides a strong, protective shield for the young child's ego system. From this foundation, children are able to venture into satisfying and meaningful social relationships, engage in playful problem solving, and face their future with an outlook of hopefulness and assertiveness.

The chances for such a positive conclusion to the period of toddlerhood rest largely on the quality of the home environment. Toddlers, with their high energy level, improbable ideas, impish willfulness, and needs for mastery, run headlong into the full range of limits in their physical and social environment. Parenting during toddlerhood is like paddling a canoe through the rapids. It requires vigilance, good communication between the bow and the stern, flexibility, and a certain *joie de vivre* that keeps the whole trip fun. A child's cognitive and social development during this period of life can be facilitated by the parents' own ego development, their style of parenting, and the quality of their relationship. The degree to which discord and conflict introduce stress into the lives of parents brings special risks for some toddlers. ●

Developmental Tasks

The use of the word *toddler* to describe development for 2- and 3-year-olds is in itself a clue to the important part that locomotion plays. In fact, it is only during the first year of this stage that the child actually toddles. By age 3, the child's walk has changed from the precarious, determined, half-humorous toddle to a more graceful, continuous, effective stride. Removal of diapers plays an important role in the progress of a child's walk. When toddlers no longer have a large wad of padding between their legs, they quickly make the transition from ugly duckling to swan.

The developmental tasks of toddlerhood—expanded locomotion, language and communication skills, fantasy play, and self-control—all contribute to the child's emerging independence within the boundaries of the social group. Some theorists refer to this as the first individuation process (Blos, 1979; Mahler, Pine, & Bergman, 1975). Obviously, 3-year-olds are not ready to set out for life alone in the big city, but they are ready to express independent thoughts, exercise some control in making choices, and do some things independently. The psychosocial crisis during this period of life—autonomy versus shame and doubt—refers to the child's struggle to establish a sense of separateness without disrupting the bonds of affection and protection that are crucial to a young child's physical survival and emotional connection to the family. In many cultures, expectations for new levels of self-sufficiency are brought about by the birth of the next child. Typically, this takes place with the support of older siblings, neighboring children, and extended family members who model and encourage more mature behavior.

Elaboration of Locomotion

OBJECTIVE 1 Describe the expansion of motor skills during toddlerhood, and explain their importance for the child's capacity to explore the environment and to experience opportunities for mastery.

Locomotion plays a central role in the toddler's psychosocial development by helping children translate their ideas into actions and by fostering new types of interactions with the social and physical environments. Imagine Harrison, kicking, throwing things, whirling around, pushing and hitting, asserting himself through the use of his motor skills to express his frustration. As locomotor skills develop, the child has new ways of remaining close to the objects of attachment, new avenues for investigating the environment, new opportunities for play, and new strategies for coping with stressful situations. For many toddlers, when frustrations build up, their anger is expressed in **tantrums**, often including an outpouring of unrestrained physical actions including hitting, kicking, flailing arms and legs, head banging, or throwing oneself on the floor. As a child's language and self-control improve, tantrums typically become less frequent, especially if adults do not inadvertently reward or reinforce them (Mayo Clinic, 2015).

Locomotion and Cognition

Growth in locomotion and cognition go hand in hand. An understanding of space, distance, and the relationship of one place to the next expand as children maneuver through their environments (Gibson & Pick, 2000). Motor activity involves continuous decision making. Functional motor activities, like getting dressed, climbing up the ladder on a slide, or pumping to make the swing go higher requires gathering information, using feedback to modify actions, and refining movement patterns to achieve desired goals. One study found that when people think about the future, their leg muscles react as if they are moving ahead, and when they think about the past, their leg muscles react as if they are moving backward (Miles, Nind, & Macrae, 2010). In toddlerhood, sensorimotor exploration may serve as the physical basis for subsequent thinking about the future (moving ahead through space) and thinking about the past (moving backward through space). Actions become increasingly goal directed and adapted to the demands of the situation. Early movements may seem jerky, unbalanced, and ineffective, but over time they become more fluid, smooth, and rhythmic. From among the variety of movement strategies that toddlers use, a few are selected and gradually coordinated. However, locomotion is always adapted to a specific environment, so when a toddler is faced with a new setting, like getting onto a swing, or crawling through a tunnel, the diversity of actions that have been cast aside may come back into use (Adolph & Robinson, 2015).

Dynamic Systems Theory and Locomotion

Dynamic systems theory has guided the contemporary view of motor development. Five factors interact to support the emergence of motor skills: (1) physical characteristics of the limbs, joints, and muscles involved in the movement; (2) changes in body weight and muscle mass; (3) new capacities in the central nervous system that improve coordination of feedback from the limbs and guide the amount of effort needed to achieve a motor goal; (4) the nature of behavioral goals; and possibly the most important of all (5) opportunities for repetition and practice (Adolph & Berger, 2006; Thelen & Smith, 1994). These factors are integrated through repeated action; as one factor changes, the others must change. In addition, these motor skills are adapted to various physical environments. Walking on sidewalks requires a different set of actions than walking in sand or on unpaved, dirt paths. As a result, although most toddlers eventually achieve the same kinds of gross motor skills, the exact path toward proficiency differs for different children and across cultural groups.

Landmarks of Motor Development

Some landmarks of motor development that are reached from ages 2 to 6—walking and running, jumping, hopping, throwing and catching, pedaling and steering—are described in Table 6.1. The development and perfection of these skills depend on opportunity and encouragement as well as on the maturation of the neurological, cognitive, and motor systems (Adolph & Robinson, 2015).

As walking becomes a more comfortable form of locomotion, new skills are added to the child's repertoire. Running and jumping are the first to emerge. By the age of 4, children are likely to leap from stairways, porches, or ladders. They have begun to imagine what it might be like to fly. Jumping is their closest approximation to flying. The actions involved in jumping form a pattern that remains stable throughout childhood and into adulthood (Clark, Phillips, & Petersen, 1989).

Children's locomotor abilities become more elaborated all through toddlerhood. For example, in films used to study the emergence of running, it appears that for toddlers, running and walking are very much alike, with little increase in velocity and little or no flight (the time when both feet are off the ground) in running. At first, toddlers appear to be running because they are moving a bit faster, but their action is not similar to adult running. Over time, however, the movements smooth out as flight time and velocity increase (Whitall & Getchell, 1995). These examples of jumping and running suggest how important early

Table 6.1 Changes in Gross Motor Skills During Toddlerhood and Early School Age

Age	Walking and Running	Jumping	Hopping	Throwing and Catching	Pedaling and Steering
2–3 years	Walks rhythmically; opposite arm–leg swing appears. Hurried walk changes to true run.	Jumps down from step. Jumps several inches off floor with both feet, no arm action.	Hops 1 to 3 times on same foot with stiff upper body and nonhopping leg held still.	Throws ball with forearm extension only; feet remain stationary. Awaits thrown ball with rigid arms outstretched.	Pushes riding toy with feet; does little steering.
3–4 years	Walks up stairs, alternating feet. Walks downstairs, leading with one foot. Walks in a straight line.	Jumps off floor with coordinated arm action. Broad jumps about 1 foot.	Hops 4 to 6 times on same foot, flexing upper body and swinging nonhopping leg.	Throws ball with slight body rotation but little or no transfer of weight with feet. Flexes elbows in preparation for catching; traps ball against chest.	Pedals and steers tricycle.
4–5 years	Walks downstairs, alternating feet. Runs more smoothly. Gallops and skips with one foot.	Improved upward and forward jumps. Travels greater distance.	Hops 7 to 9 times on same foot. Improved speed of hopping.	Throws ball with increased body rotation and some transfer of weight forward. Catches ball with hands; if unsuccessful, may still trap ball against chest.	Rides tricycle rapidly, steers smoothly.
5–6 years	Increased speed of run. Gallops more smoothly. True skipping appears.	Jumps off floor about 1 foot. Broad jumps 3 feet.	Hops 50 feet on same foot in 10 seconds. Hops with rhythmical alternation (2 hops on one foot and 2 on the other).	Has mature throwing and catching pattern. Moves arm more and steps forward during throw. Awaits thrown ball with relaxed posture, adjusting body to path and size of ball.	Rides bicycle with training wheels.

locomotor activity is in establishing motor skills that become elements of more complex athletic abilities in later childhood, adolescence, and adult life.

Locomotion and Play

Locomotor skills figure prominently in the increasing complexity of play. At first, youngsters may run for the sake of running. They practice over and over again. Later in toddlerhood, running changes from a kind of game in itself to a valuable component of many other games. The absolute speed of toddlers is limited by their somewhat precarious balance and short legs. This does not discourage them, however, from devoting a great deal of time and energy to running. The goals of mastery and getting to new places for exploration are too strong to dampen their enthusiasm. Locomotor play provides practice for coordinated movement in a risk-free context. Through locomotor play, toddlers can develop new skills and perfect actions that become useful for later activities, such as running to catch the bus or hopping over a big mud puddle. Locomotor play eventually becomes incorporated into the games and sports of early and middle childhood (Pellegrini, 2011).

Toddlers are often exposed to a wide variety of forms of locomotion, such as swimming, skiing, skating, sledding, and dancing. Children seem eager to use their bodies in a variety of ways, and they learn quickly (Goodway, Ozmun, & Gallahue, 2012). As their physical coordination improves, children engage in new large-muscle activities: climbing, sliding, swinging, pounding,

Courtesy of Philip Newman

Toddlerhood brings tremendous advances in movement, coordination, and balance. You can see the sense of accomplishment in Micah's face, having climbed up the big log blocks and getting ready to leap off.

digging, and rough-and-tumble play. Locomotor play provides immediate benefits to children in terms of physical fitness, including increased bone density, cardiovascular fitness, and flexibility (Pellegrini, 2009). Certain forms of physical activity provide an important source of information about the physical self. Toddlers enjoy their bodies and are generally joyful when in the midst of physical play. Thus, physical activity contributes in an essential way to the toddler's self-concept.

To the extent that coping involves the ability to maintain freedom of movement under conditions of threat, locomotor skills acquired during toddlerhood provide resources for lifelong strategies for fight or flight. Advanced locomotor skills may also increase conflicts with caregivers, introducing new struggles of willfulness and new parental constraints.

> When Ellen was about 2½ years old, she enjoyed watching her older brother climbing up a tree in the neighbor's yard. She would beg her brother to lift her up so she could get into the tree with him. One afternoon, Ellen's brother lifted her into the tree and then ran off to play with a friend. Ellen tried to get down from the tree, but she got her foot stuck in a crack between the branches. She cried and yelled until her mom came to get her. Ellen's mom scolded her for being in the tree and warned her never to go up there again. But the next afternoon, Ellen was back trying to figure out how to climb into the tree on her own.

From this example, one can see that when locomotor skills occur early in a developmental period, before the maturation of verbal and cognitive competence, toddlers may find themselves at odds with caregivers who must limit locomotion to protect the child's safety. Caregivers may also have to limit a toddler's locomotion to secure the safety of other people and objects in the environment.

Motor Impairments

Children who lack muscle strength or coordination may experience strong feelings of frustration as they struggle to keep their balance, throw or catch a ball, or use their hands and feet to perform new tasks. A number of conditions, including motor skills impairment (sometimes referred to as motor dyspraxia) and neurological diseases such as muscular dystrophy or cerebral palsy, impede the maturation of locomotion and other motor skills. Although children may be diagnosed with the same motor impairment condition, the exact impact on their functional capacity for locomotion can differ. For example, some children with motor skill impairment are described as clumsy; they may drop items or run into walls and furniture. Some may have difficulty using a cup, spoon, or fork to eat or have difficulty holding a pencil and learning to print. Others have frequent accidents due to motor planning difficulties (eMedicinehealth, 2015).

Young children with these conditions can benefit from guided activity-focused interventions that improve their ability to participate in functional activities, allowing them to enjoy interacting with family members and peers. With the help of physical and occupational therapists and parents, specific interventions can be designed to enhance functional motor activity, and improve coordination and control. Three steps are suggested to help design interventions that will foster motor advances (Valvano & Rapport, 2006, p. 294):

1. Develop activity-related goals and objectives in cooperation with the family's priorities and values that will increase a child's ability to participate in daily routines.
2. Plan activity-focused interventions that include frequent opportunities for practice throughout each day. These interventions should be designed to address impairments due directly to the diagnosed disorder, but incorporate the child's strengths and interests, as well as principles observed in typically developing children.
3. Integrate impairment-focused interventions that include remediating possible secondary impairments such as weakness from disuse, muscle strain, or postural problems that have emerged over time in efforts to cope with the primary limitations.

Since functional movement is intricately connected to the environmental conditions, interventions need to incorporate environmental modifications that make it possible for a child to experience success. These might include creating physical supports for upright sitting, positioning objects at a level that allows the child to reach them without losing balance, or creating a nonskid surface to enhance walking. Over time, as the child's abilities improve, these environmental parameters may be altered or eliminated. In the end, movements need to be flexibly adapted to achieve goals in varied environments. Thus, interventions have to incorporate opportunities for children to use their problem solving abilities to modify their approaches, even when impairments constrain certain actions.

FURTHER REFLECTION *What do you remember from your childhood about locomotor activities? Do you recall riding a tricycle, swinging, running, going down the slide, or swimming? In what ways do motor skills continue to contribute to your sense of autonomy and mastery as an adult?*

What observations would lead you to think that a toddler had a motor impairment? Who would you contact to help identify this kind of problem? What interventions might be possible?

Language Development

OBJECTIVE 2 Summarize the accomplishments in language development and outline the features of the language environment that support communicative competence.

Jean Piaget (1970) described the years from about 2 to 5 or 6 as the stage of **preoperational thought**. During this stage, the sensorimotor schemes that were developed during infancy are represented internally. The most significant achievement of this new stage of cognitive development is the capacity for semiotic or *representational* thinking—understanding that one thing can stand for another.

In **semiotic thinking**, children learn to recognize and use symbols and signs. **Symbols** are usually related in some way to the objects for which they stand. The cross, for example, is a

APPLYING THEORY AND RESEARCH TO LIFE

How the Brain Processes Language

With the use of positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), one can observe different areas of activity in the brain related to varying language activities, including speaking, seeing words, and hearing words. The areas of the brain that become more visible following a task are assumed to have been activated by the task (Campbell, MacSweeney & Waters, 2007).

In infancy, both hemispheres are involved in language perception. By the end of the third year, for the vast majority of right-handed children, the essential aspects of speaking and understanding spoken language typically become focused in the left hemisphere of the brain. For left-handed children and those who are ambidextrous, these aspects of language are focused in the right hemisphere (Oates, Karmiloff-Smith, & Johnson, 2012).

The nondominant hemisphere becomes important for understanding features of language such as interpreting the emotional tone of the speaker, humor, and metaphor. However, neuroimaging studies have demonstrated that many regions of the brain are involved in language production and comprehension (Gernsbacher & Kaschak, 2003; see FIGURE 6.1 ▶).

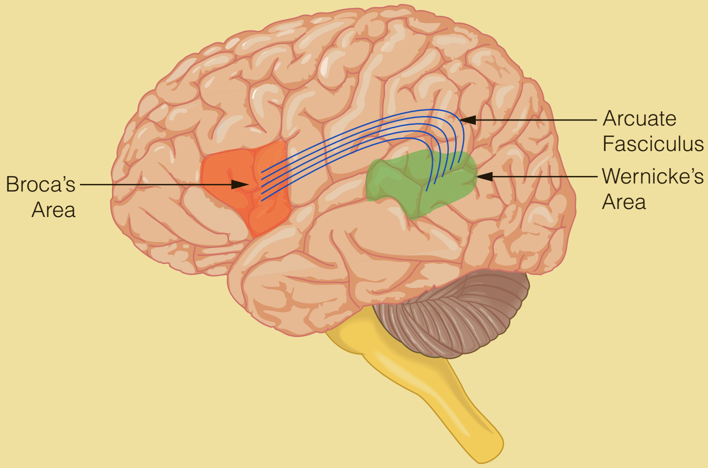

FIGURE 6.1 ▶ Three Areas of the Brain That Are Intimately Related to Speech: Broca's Area, Wernicke's Area, and the Arcuate Fasciculus, a bundle of nerve fibers that connects the two.

You can appreciate how complex language comprehension is and why it must engage many brain areas. In what seems like an instant, the sounds someone else makes are heard and interpreted. This requires attention, recognition of word sounds and meanings, and the flexibility to recognize language from a variety of speakers who use different expressions, tones of voice, and dialects in their speech (Cutler, 2012). Studies that monitor brain activity find that nouns and verbs, the kinds of words that are especially important for conveying meaning, are associated with different patterns of activity than prepositions and conjunctions, the kinds of words that are more important for grammatical information.

Damage to localized areas of the brain leads to a loss of the ability to speak referred to as **aphasia**. Damage to Broca's area results in an inability to produce speech, but language comprehension remains functional. Damage to Wernicke's area does not affect the ability to produce language, but understanding is lost. People with Wernicke's aphasia can produce words clearly, but the words do not make sense. People who have damage to the arcuate fasciculus can understand language, but their speech does not make sense, and they cannot repeat words. In a condition called *aprosodia,* people have difficulty talking about their emotions when there is damage to the area of the right hemisphere that mirrors the area of the left hemisphere that is used for language.

Speech is different from other cognitive functions related to communication, such as word meaning or symbolizing an idea by drawing a picture (Sanders, Weber-Fox, & Neville, 2008). In addition to the areas of the brain identified in Figure 6.1 as especially key for language production and comprehension, speaking involves the motor cortex, reading involves the visual cortex, and understanding spoken language involves the auditory cortex. The task of reading aloud involves the visual cortex, motor cortex, and Broca's area.

What about sign languages? Are they processed in the brain the same way as spoken language? Studies of this question are leading to the following conclusion: Both spoken language and sign language engage the same left hemisphere areas for language production and comprehension, including Broca's area and Wernicke's area. The right hemisphere supports other aspects of language, especially appreciation for how sentences or phrases are linked together, and the rhythm or melody of the communication. It is also activated in social communication, including the pragmatics of language, facial expressions, gestures, and tone of voice. This is true whether the person is a native speaker or a native signer. However, there is some evidence that sign language engages more of the right hemisphere, especially the simultaneous processing of visual/spatial information and the large grain information contained in gestures (Campbell, MacSweeney, & Waters, 2007).

Language production capacities of the brain demonstrate both sensitive periods and remarkable plasticity. Sensitivity is evidenced by the impact of delayed exposure to language on disruptions in grammar. Sensitivity is also observed as infants lose their ability to differentiate language sounds that are not spoken in their home environment. Plasticity is evidenced in research comparing children who had congenital left hemisphere damage with adults who had left hemisphere injuries. The children scored much higher than the adults on measures of spontaneous speech, suggesting that other areas of the brain had taken over many of these functions (Bates et al., 2001).

Critical Thinking Questions

1. Explain how it is possible that the brain shows both sensitive periods and plasticity regarding language competence.
2. Describe some differences between vocabulary and grammar. Explain the different brain functions that are needed for these two aspects of language.
3. Hypothesize about the impact of the language environment on the development of the neural basis of language. Consider these three contexts: parents who engage their children in frequent conversations; parents who speak in harsh, threatening voices to each other and to their children; families in which many people are speaking at once. How might each of these environments influence the way the brain processes language?

symbol of Christianity. In pretend play, a scarf or a blanket may be a symbol for a pillow or a dress. **Signs** stand for things in a more abstract, arbitrary way. **Words** are signs; there is no direct relation between the word *dog* and the animal to which the word refers, yet the word stands for the object. For adults, it seems natural to use matchsticks or little squares of cardboard to represent people or buildings, but for children, the idea that a stick may be a car or a horse is a dramatic change in thinking that emerges gradually during the preoperational period.

Five representational skills allow children to manipulate objects mentally rather than by actual behavior: (1) imitation in the absence of the model, (2) mental images, (3) symbolic drawing, (4) symbolic play, and (5) language. **Representational skills** allow children to share their experiences with others and to create imagined experiences. These skills also free children from communicating only through gestures and opens up opportunities to communicate about the past or the future as well as the present. Children can express relationships they may have known in the past by imitating them, drawing them, talking about them, or acting them out in fantasy. They can also portray events and relationships that they wish would occur or that they wish to alter (Nelson, 2010). In this and the following sections, we focus on two of these representational skills, language and fantasy play, which are among the most notable achievements of toddlerhood and are foundational for psychosocial development across the life span.

Communicative Competence

In the process of language development, children acquire **communicative competence**. They become adept at using all the aspects of language that permit effective participation in the **language environment** of their culture (Hill & Kuczaj, 2011; MacWhinney, 2015). This includes producing the sounds of the language; understanding the system of meanings, the rules for word formation, and the rules for sentence formation; developing a rich vocabulary; making adjustments to the social setting that are necessary to produce and interpret communication (*pragmatics*); and acquiring the ability to express thoughts in written as well as oral form. Through the achievement of communicative competence, children become increasingly integrated into their culture. They learn the expressions, tones of voice, and gestures that link them intimately to the language environment of their home and community. They learn when to speak and when to remain silent. They learn how to communicate with peers, parents, and authority figures. They learn the terms applied to kin, close friends, acquaintances, and strangers; the words that are used to disparage or devalue; and the words that are used to recognize and praise. Although much of communication is intended to create shared meaning between the sender and the receiver of messages, sometimes communicative competence is used to deceive, mislead, or intimidate (Fiedler, 2008). If nurturing is the primary vehicle for cultural socialization in infancy, communication is the primary vehicle in toddlerhood. A discussion of how the toddler's brain processes language is presented in the **Applying Theory and Research to Life** box.

Communicative competence begins during infancy and develops across the entire life span. Vocabulary, grammar, and pragmatics continue to be refined as one engages in formal schooling and diverse social settings where specific words, expressions, and styles of interaction are in use. But toddlerhood is the time of a dramatic expansion in verbal competence when remarkable achievements are made in an exceptionally brief period. The following discussion of language and communication is divided into two major sections: (1) language milestones and (2) the language environment. The first section outlines the pattern of communication accomplishments of toddlerhood, including the expanded use of words with meaning, the formation of two-word sentences, and more complex sentence formation. The second section identifies factors in the psychosocial environment that help facilitate and optimize communicative competence.

Language Milestones in Toddlerhood

The text provides an overview of patterns of accomplishment in language and communication from infancy through about age 4. As you may remember, many of the precursors of spoken language, including language perception, babbling, and gesturing, were discussed in chapter 5. Certain sequences or developmental milestones appear to be quite common among children from many language environments. Communicative gestures precede the production of spoken words, and the production of a substantial vocabulary of spoken words precedes the linking of words into two-word sentences. However, it is important to recognize the wide variability in the development of communicative skills.

The timing of the onset of various abilities and their rate of growth vary from child to child. At 20 months, Sadie would talk about her experiences in a rapid profusion of sounds and expressions that were completely unintelligible. She was telling her story in her own private vocalizations. By 30 months, Sadie could tell you in "real" words and phrases what she does or does not want to eat or wear, what happened in school, or when she wants to go outside, read a book, or play a certain game. In contrast, many toddlers at this same age are poorly understood even by family members and have a very limited vocabulary. In a large national study of infant/toddler language, word production for 12-month-old infants ranged from the 90th percentile, who used 26 words or more, to the 10th percentile, who produced no words (see FIGURE 6.2 ▶). By 16 months of age, those in the 90th percentile were using 180 words, and those in the 10th percentile produced 10 words or less (Fenson et al., 1994). All these children were healthy, normal children, with no known history of developmental delay, prematurity, or genetic disease. As you read about typical patterns, try to remember that these patterns disguise important variations.

Language development in toddlerhood brings rapid acquisition of a wide-ranging vocabulary and the initial use of a primitive grammar that is quickly transformed into the grammar of the spoken language. The typical developmental progression in language competence is characterized by three common patterns: (1) an acceleration in the production of single words, followed by two-word combinations; (2) a predominance of nouns in the vocabulary followed by the addition of verbs, adjectives, and prepositions; and (3) two-word utterances followed by longer strings of words organized by use of grammatical rules that include indicators of meaning, such as possession, plural, and past, present, and future (Owens, 2015).

A universal capacity for language matures rapidly in the first 4 years of life. Each of the approximately 6,000 languages spoken in the world today is capable of doing roughly the same thing, conveying ideas. However, each language has its own vocabulary and grammar, which have to be learned specifically. Whereas there may be a universal capacity to recognize certain facial expressions as happy or sad, or even certain gestures that mean "give me" or "pick me up," there is no universal human code that links objects, ideas, or actions to spoken words and sentences. Each human child has to learn a particular spoken language. This uniqueness of language contributes to its flexibility, leading to the creative use of language and its capacity to express novel thoughts and ideas (Wargo, 2008).

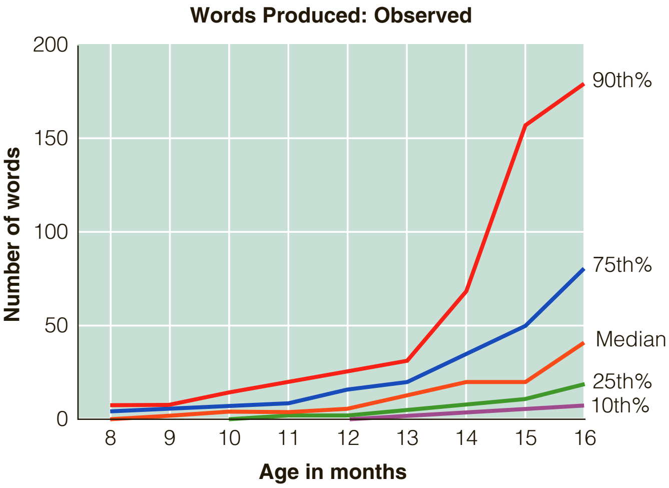

FIGURE 6.2 ▶ Word Production from 8 to 16 Months

Source: From "Variability in Early Communicative Development," by L. Fenson et al., 1994, Monographs of the Society for Research in Child Development,1994, 59 (5), 38. Copyright © 1994 The Society for Research in Child Development, Inc.

Vocabulary. During the period from 12 to 16 months, infants make significant progress in learning the names of objects and applying them to pictures or real examples. There is a rapid expansion of vocabulary during these 4 months from few or no spoken words to about 26. Vocabulary continues to expand at a rapid rate throughout the toddler and early school years (Booth, 2009). The average toddler of 30 months has a spoken vocabulary of about 570 words. In order to accomplish this feat, children seem to *fast-map* new meanings as they experience words in conversation. To **fast-map** is to quickly form an initial, partial understanding of a word's meaning. It is an information-processing technique in which children relate the new word to the known vocabulary by linking it to known words and concepts that are already well understood. The child has to hear the new word only a few times in a context that makes its meaning clear. In day-to-day life, children hear thousands of words, many over and over again, without necessarily knowing their meaning. However, once children recognize the link between a word's sound and its meaning, they can quickly associate other familiar word sounds with their meanings (Swingley, 2007). Thus, without direct word-by-word tutoring, children accumulate numerous samples of their culture's language from the speech they hear and attach a minimally satisfactory definition to each word or phrase. This vocabulary burst is associated with speed of processing in word recognition. Young children who recognize words with greater speed also seem to have a greater vocabulary. The combination of speed of word recognition and vocabulary size in early toddlerhood are strong predictors of subsequent language and cognitive skills in middle childhood (Marchman & Fernald, 2008).

The early phase of vocabulary development seems to focus on broad semantic categories—animals, vehicles, fruits, clothes, and so on. New words, particularly nouns, are treated like the name of a category of things rather than of only one specific object or a part of it. For example, when a child learns the word *cup*, it is used to refer to all objects that have the general shape and function of a cup. A much slower process of vocabulary development occurs as children and adults learn the distinctions among words within categories (McDonough, 2002). Toddlers may have a clear idea about the difference between dogs and cats and use these words correctly, but they do not yet know about the distinctions among the various types or breed of cats or dogs. This requires careful observation and new learning. Many books written for young children take up this kind of vocabulary building by presenting pictures of the many different types of a larger category—the different animals at the zoo; the different flowers in the garden.

Two-Word Sentences. At 16 months of age, few children make two-word sentences, but by 30 months almost all children make them (Fenson et al., 1994). These two-word sentences are referred to as **telegraphic speech**. Children merge two words into phrases that are essential to communicate what they intend to say. Just as in a telegram, however, other words—verbs, articles, prepositions, pronouns, conjunctions—are left out. A child will say, "my ball," "more juice," and "Daddy gone." Before this point, children tend to utter single words accompanied by gestures and actions. By stringing two words together, they convey more meaning through verbal communication and rely less heavily on gestures and actions. The acquisition of telegraphic speech allows a child to make greater use of the symbolism inherent in language to communicate meaning (Powers, 2002).

Children are quite innovative in using two-word sentences. They continue to understand more than they are able to say, but they appear to use their limited vocabulary and the newfound ability to combine them to get their point across. Children may convey different meanings with the same sentence. "Daddy go," for example, may be used to tell someone that Daddy has left, or it may be used to tell Daddy to leave. Children often indicate their meanings by tone of voice or by the words they stress. The use of two-word sentences is characteristic of toddler-age language learners in many cultures (MacWhinney, 2015).

Martin Braine (1976) analyzed the first word combinations spoken by children in English, Samoan, Finnish, Hebrew, and Swedish. His goal was to identify the kinds of rules or patterns that governed these early combinations. Ten patterns of word combination were embedded in those early language samples:

1. Making reference to something: See + X (*see mother*)
2. Describing something: Hot + X (*hot stove*)
3. Possession: X has a Y (*Billy has a bottle*)
4. Plurality: Two + X (*two dogs*)
5. Repetition or other examples: More + X (*more up*)
6. Disappearance: All gone + X (*all gone milk*)
7. Negation: No + X (*no sleep*)
8. Actor-action relations: Person + X (*Daddy sleep*)
9. Location: X + here (*Grandma here*)
10. Requests: Have + X (*have it, ball*)

Braine found that he could identify some common patterns of word combinations. However, these combinations were not guided by the grammatical categories of the spoken language. Rather, they were guided by the meanings the child wished to express and by the variety of objects, people, and interactions in the immediate environment. The patterns of word combinations used by some children did not overlap at all with those used by other children in the same culture.

Early language is closely tied to the representation of sensorimotor schemes—the activities that dominate the child's life, such as eating, sleeping, playing games with mommy or daddy or siblings, going places, coming back home, and so on. It expresses the properties and relationships of the objects and people that are important in a child's life. Language use emerges within a larger communication system and reflects a child's cognitive capacities. At the same time, it reflects the perceptual and functional characteristics of the environment. Vocabulary and grammar grow hand in hand. As toddlers learn more words, they use them in combination to express more complex ideas (Bates & Goodman, 2001). Underlying this remarkable blossoming of language expression is the child's motivation to become part of his or her social community. Language brings children closer to those they love by allowing them to share thoughts and feelings in ways that can be understood (Nelson, 2007).

Grammatical Transformations. By combining words according to the rules of **grammar** for a given language, a person can produce a limitless number of messages that can be understood by another person. Remarkably, by the age of 4, children appear to be able to structure their sentences using most of these rules without any direct instruction. Consider the difference in meaning between "The boy hit the ball" and "The ball hit the boy." The simple matter of word order in a sentence is critical for preserving meaning. The basic format of an English sentence—noun phrase followed by verb phrase—is a central part of its grammar. In order to ask a question or produce a negative sentence, the speaker transforms this word order according to a specific set of rules (e.g., "You are going" versus "Are you going?"). The addition of certain inflections and modifiers conveys information about time, possession, number, and relation. As children learn the grammatical transformations of their language, they become much more effective in conveying exactly what they have in mind.

A surprising observation is that children use correct transformations for the past tense of irregular verbs (*went, gave, run*) before they use correct inflections of regular verbs (*talked, walked, jumped*). It appears that children first learn the past tense of irregular verbs through rote memory. Once they learn the rule for expressing the past tense by adding *ed*, they occasionally **overregularize** this rule and begin making errors in the past tense. Thus, a 2-year-old is likely to say "I ran fast," but a 3-year-old may say "I runned fast." According to a model proposed by Gary Marcus, children recognize and have a symbolic category for words that are verbs. They establish a default rule: "To form the past tense, add *ed* to any word that can be categorized as a verb." They also memorize the past forms of the irregular verbs as they encounter them. When an irregular verb is required, its irregular past tense form is always used if the child can recall it. However, if the child cannot recall the past tense, or if the word is novel, the default rule is called into play. In a study of preschoolers, the rate of overregularization was 4.5 percent. This fell to 2.5 percent for first graders and 1 percent for fourth graders, suggesting that as a child's vocabulary grows, the need to apply the default rule to unfamiliar verbs declines (Marcus, 1996).

The grammatical errors that young children make alert us to the fact that they are working to figure out a system of rules with which to communicate meaning. It is unlikely that these errors result from imitation of adult speech. Children say such things as "My do it" or "Dose mines." They have certainly not copied those expressions from adults; rather, these errors suggest the beginning of a grammar that becomes more specialized and accurate as children acquire the opportunity to match their speech to that of others. One can catch toddlers in the act of building their grammar by listening to them revise their own speech. From the age of 2 to 4, as their grammar matures, toddlers will pause in midsentence and revise their speech to make a more complex or complete expression. Aware of linguistic alternatives, they stop to select one that best expresses their thoughts in a specific language environment (Rispoli, 2003).

The milestones in language development from 24 months to age 4 are summarized in Table 6.2. In the second year of life, babies understand words and phrases. They develop a vocabulary and begin to form two-word phrases. During the third year, language is definitely used to communicate ideas, observations, and needs. Comprehension of spoken language seems almost complete. Some speech may not be easily understood by people outside the family, partly because these children are unable to produce clear phonetic sounds and also because their knowledge of adult grammar is limited. During the fourth year, most children acquire an extensive vocabulary. They can create sentences that reflect most of the basic rules of grammar. Their language is a vehicle for communicating complex thoughts that are usually understood by children and adults outside the family. They can use their communicative skills to participate in social exchanges with other children, talk about their experiences, make plans, and resolve conflicts.

Table 6.2 Milestones in Language Development from 24 Months to 4 Years

At the Completion of	Language Skills
24 months	Enjoys listening to and hearing stories; speaks about 50 words; links two or more words together; makes up language using their own creations (e.g. "No paper daddy."); uses some adjectives like *big* or *silly*; speaks clearly enough for parents to understand.
30 months	Vocabulary of more than 300 items (some children seem to be able to name everything in the environment); many new additions every day; no babbling; uses two- and three-word phrases to talk about and ask for things; definite increase in communicative behavior and interest in language; use of linguistic suffixes for possession, plural, and past tense; frequent use of irregular plural noun (foot/feet) and irregular verbs; comprehension is not very good yet by those unfamiliar with the child's speech.
36 months	Vocabulary of 500–1,000 words; speaks in three- and four-word sentences; uses pronouns like *I*, *you*, and *we*; asks for and directs attention to objects and activities by naming them; can follow multiple requests (e.g., "bring me the book and sit on the couch"); speech is understood more readily by familiar language partners.
48 months	Answers simple questions; speaks in complete sentences; uses parts of speech like other native speakers; talks about activities that took place at child care, with friends, or in other settings; people outside the family can usually understand the child's speech.

Adapted from Mayo Clinic Infant and Toddler Health, 2013. American Speech-Language Hearing Association, 2013.

The pattern of language milestones is common across languages and similar for toddlers who are learning a second language. In an investigation of international adoptees, researchers compared English language acquisition for children who had been adopted from China and U.S.-born monolingual (one language) infants (Snedeker, Geren, & Shafto, 2007). The Chinese children were between the ages of 2½ and 5½ when they were adopted. They were compared to U.S. infants between the ages of 1½ and 2¾. Language competence was assessed every 3 months until the Chinese children had been in the United States 18 months. These adopted children were learning English in much the same way that babies of English-speaking parents learn the language—from exposure to English in the family environment. They had the advantage of more advanced cognitive maturation and experience learning a first language and the disadvantage of delayed exposure to English during infancy.

Three features of language learning were observed among the Chinese adoptees: (1) They showed the same pattern of language production as monolingual infants, using one-word utterances at first, which were mostly nouns with other kinds of words added over time. (2) During their first 3 months in the United States, the adopted children acquired English vocabulary at a rate four times faster than comparable monolingual infants. This suggests that prior experience coupled with advanced understanding of the object-word link contributed to an accelerated process of vocabulary learning. (3) Both adopted children and monolingual infants showed the same positive correlation between vocabulary size and sentence complexity. Neither infants nor adoptees whose vocabulary was less than 300 words produced multiword expressions. Thus, despite their advanced cognitive maturation and prior exposure to another language, adoptees seemed to go through the same sequence of problem-solving steps to build grammatically complex sentences that are characteristic of monolingual infant language learners.

Pragmatics. Children use language to participate in social interactions. A child may have a rich vocabulary and may be able to form grammatically correct sentences that are understood by others, and still use language inappropriately. **Pragmatics** includes three basic skills: using language for different purposes such as asking a question, giving information, or asking for help; changing language depending on the listener, for example, speaking to a younger child or an adult, or speaking to a class of other children as compared to one friend; and following cultural rules for language, for example, taking turns in a conversation or using appropriate facial expressions and gestures to supplement one's verbal communications (American Speech-Language-Hearing Association, 2016).

Language is a tool for explaining your thoughts and getting what you need from others. It is a source of entertainment through storytelling, reading books, singing, poetry, jokes, and games. As children become increasingly embedded in their culture and community, the pragmatics of their language matures. They learn politeness rules, rules for inferring information from someone's communications, and rules for taking part in dyadic and small group conversations (Hwa-Froelich, 2015). As you review the language milestones in Table 6.2, notice certain features of pragmatics, including a child's ability to answer questions about a story, respond to a request, ask for things, retell an experience, and tell stories to others.

Language Development Beyond Toddlerhood. Although the fundamentals of language are well established by age 4, vocabulary and accompanying word meaning are still far from complete. For example, Mary may raise a fuss about wanting the biggest piece of cake. If you allow her to make a choice, she selects a piece with lots of frosting. Clearly, the word *biggest* is not being used correctly. Even though Mary is able to memorize and repeat the words *big, bigger*, and *biggest,* she does not yet fully understand the concept to which they refer.

As the process of fast-mapping implies, young children may add a word to their vocabulary without understanding the several meanings that this word has in different contexts. During the periods of early and middle childhood, considerable time and attention are devoted to exploring vocabulary, correcting some meanings that were incorrectly learned, and expanding the full range of meanings and underlying concepts that are linked to the many words that were acquired so rapidly during toddlerhood. One estimate is that the reading vocabulary or comprehension of dictionary entries of a 10-year-old child is close to 40,000 words, with another 40,000 proper names, places, and expressions unique to the child's own family, neighborhood, and cultural group (Anglin, 1993).

After toddlerhood, children become increasingly able to use language to guide and control their behavior. Two- and three-year-olds have difficulty using verbal instructions to control or guide their behavior. They may be able to tell themselves to "stop" or "go slow," but these commands are not effective in slowing them down. As their vocabulary and cognitive abilities increase, children become better at using language to reinforce, modify, or disrupt their behavior. The development of language is an integral feature of the maturation of self-control, a developmental task that is discussed further on in this chapter (Beaver, DeLisi, Vaughn, Wright, & Boutwell, 2008; Hebert-Myers, Guttentag, Swank, Smith, & Landry, 2006; Vallotton & Ayoub, 2011).

Important language functions develop more fully during early and middle childhood. As their understanding of the self and the social environment expands, older children use language to plan a problem-solving strategy, guide a complex series of motor activities, or identify the relationships among objects. Vocabulary expands, and words are used more frequently in the ways they are used in adult speech. Depending on the nature of their conversational partners at home and school, children's sentences become more complex, including conditional and descriptive clauses. The irregular verbs and nouns are learned and used correctly. As children attend school, they learn to conceptualize the grammatical structure of their language. Pragmatics also matures. Children learn patterns of polite speech as well as slang. They learn to distinguish between expressions that communicate *probability* (e.g. "I'll try to be there to pick you up at 4:30," or "The ball may have rolled under the couch") versus *certainty* (e.g. "I'll be there promptly at 4:30," or "The ball rolled under the couch") (Ozturk & Papafragou, 2015). Language skills contribute to a child's ability to interact with peers, planning, coordinating, and explaining their ideas in the context of play.

Laura Dwight/PhotoEdit

Toddlers can use their language to enhance play and foster cooperation.

Beyond the formal elements of vocabulary, grammar, pragmatics, reading, and writing, language becomes a vehicle for creative expression. Children write poems, essays, and stories. They begin to use sarcasm, puns, and metaphors to elaborate their speech. They create secret codes with their special friends. Children make up riddles and jokes, put on plays and puppet shows, work on school newspapers, and leave enigmatic or corny messages in their friends' yearbooks. As children move into early and later adolescence, they begin to supplement their communication with the use of social media. They may use new codes or symbols to share private information with peers. Through the use of text messaging and Twitter, forms of expression have been invented that abbreviate or condense meaning. If you participate in these modes of communication, you quickly learn the meanings of these symbols and signs.

Language plays a critical role in the resolution of subsequent psychosocial crises, especially the establishment of group identity, intimacy, and generativity. It is primarily through the quality of one's spoken language that one achieves the level of disclosure that sustains friendships and subsequent intimate relationships. Language also serves as a mechanism for resolving conflicts and for building a sense of cohesiveness within groups, whether of friends, coworkers, or family members.

The Language Environment

In this section, we focus primarily on the nature of the interaction between toddlers and their caregivers, with some attention to the issue of bilingualism and the relationship of the language environment at home and school. Language is a cultural tool, a means for socializing and educating young children. It is one of many inventions for creating a sense of group identity and for passing the mythology, wisdom, and values of the culture from one generation to the next. Competence in the use of language solidifies the young child's membership in the immediate family and in the larger cultural group.

Although there is strong evidence for genetically based origins of the capacity for language learning, the specific content and tone of a child's communication are strongly influenced by the language environment. In many industrialized cultures, children are separated from the world of adult work. Special educational settings are created to prepare children for the tasks of adulthood, and adults interact with children in specific ways that differ from their interactions with other adults. In other cultures, children are present in the midst of ongoing adult activities. Children are encouraged to become active listeners and observers, gradually participating in conversations and work as their abilities permit. Thus, the nature of the interactive language environment, the expectations for children to participate, and the kinds of communications that children are likely to engage in can vary based on the broad cultural orientation about the place and role of children in the larger society (Rogoff & Angelillo, 2002; Rogoff, Morelli, & Chavajay, 2010; Rogoff, Paradise, Arauz, Correa-Chavez, & Angelillo, 2003).

Interaction and Language Development. Of all the many ways that caregivers contribute to a child's cognitive growth, possibly the most important is the opportunity for language interactions. Brain development in infancy and toddlerhood is stimulated by exposure to adult language through conversation, baby talk, and reading aloud. Language development emerges in a social context. Caregivers and children engage in a dynamic pattern of talk: Infants make vocalizations to which caregivers respond; caregivers engage in a flow of infant-directed talk to which infants respond. Contingent interactions are a powerful tool for promoting language learning (Ko, Seidl, Cristia, Reimchen, & Soderstrom, 2015). An interactive human being can respond to a child's questions, provide information, react in unexpected ways and surprise the child, explain plans or strategies, and offer praise or criticism. The frequency and quality of parent–child interactions are closely associated with children's social and cognitive competence (Hart, Newell, & Olsen, 2003). The **Human Development and Diversity** box discusses **bilingualism**, the complex learning process that takes place in children who are brought up in families that speak two languages.

The link between the frequency of parent–child interactions and the child's verbal competence is well established. Three different explanations have been suggested to account for this link:

1. Parents and their offspring share a genetic predisposition for verbal competence that is evident in the frequency of parent–child interactions and in the early acquisition of verbal skills.
2. Parents who interact frequently with their children provide a rich array of verbal stimuli and thereby promote high levels of verbal comprehension and production.
3. Children who are more verbally competent stimulate more interaction from their caregivers; this establishes a more active and diverse verbal environment.

Certain characteristics of a language partner facilitate a child's language acquisition and communication skills (Singh, Morgan, & Best, 2002; Snow, 1984). When using infant-directed speech, adults tend to speak in a high pitch, use shorter sentences, speak slowly, use a limited vocabulary, use attention-getting strategies, and speak in a friendly, positive tone. Even older children will modify their speech when interacting with toddlers to hold their attention and guide their behavior. Caregivers have been observed to modify their speech in the following ways so that they are more likely to be understood (Golinkoff, Can, Soderstrom, & Hirsh-Pasek, 2015; Mitchell, 2001; Soderstrom, 2007):

1. They simplify utterances to correspond with the toddler's interests and comprehension level.
2. They emphasize the here and now.
3. They use a more restricted vocabulary.
4. They do a lot of paraphrasing.
5. They use simple, well-formed sentences.
6. They use frequent repetitions.
7. They use a slow rate of speech with pauses between utterances and after the major content words.

These characteristics of caregiver speech are not universal; rather they reflect cultural norms for addressing infants and toddlers. They are most typically observed in middle-class, European American families. In one cross-cultural analysis, for example, African American adults in the rural South were observed in interaction with their children (Heath, 1989). Adults did not simplify or censor their speech for young children. They frequently did not address children directly but expected the children to hear what they said and to interrupt if they had something to add. Adults and children directed one another's behavior with specific commands. It was just as acceptable for a toddler to command an adult as the other way around. Adults teased children, especially in the presence of others, in order to give the children a chance to show off their quick wit and to practice assertiveness. Within this language environment, children had the opportunity to hear a variety of opinions, gather information to extend their direct experience, and observe shifts in language tone and style that accompany changes in the topic or purpose of the conversation. This example illustrates the variation in communication styles that characterize the language-learning environments of American families.

Other research describes variations in the nature and amount of parent–child interaction that take place during a typical day (Huttenlocher, Vasilyeva, Waterall, Vevea, & Hedges, 2007). In one longitudinal study, 40 families were observed once per month over 2½ years (Hart & Risley, 1992). The observations covered the period shortly before, during, and after the child was learning to talk. The results of the study illustrate the differences in language environments in families. The number of words spoken to a child in an hour varied from 232 to 3,606; the percentage of time that parents were in the same room as the child ranged from 38 percent to 99 percent; and the average number of times that parents and children took turns in an interaction ranged from 1.8 to 17.4.

In addition to documenting differences in the amount of parent speech directed toward children, the study found that the quality of a parent's speech toward the child was positively related to the child's IQ at 37 months of age. A systematic relationship was

HUMAN DEVELOPMENT AND DIVERSITY

Bilingualism

Children all over the world speak more than one language without any problems. The rise in the number of Asian and Latino immigrants to the United States has led researchers to investigate the process through which young children manage the challenges of learning and speaking two or more languages. Children who grow up in multi-lingual families and who continue to have access to multiple languages in early childhood appear to benefit, as evidenced by fewer internalizing and externalizing problems as they enter middle childhood (Han & Huang, 2010).

Young bilingual children are adept at switching from one language to another as the conversational situation demands. This is referred to as **code switching**. In one study of bilingual Latino children in Miami, Florida, the children had access to two vocabularies, one in Spanish and one in English. Rather than knowing two words for the same thing, these vocabularies did not overlap much. Knowing the two languages actually expanded the concepts children could use to express their thoughts in comparison to children who spoke English or Spanish only (Umbel, Pearson, Fernandez, & Oller, 1992).

Code switching begins at a very early age. Infants growing up in multilingual families begin to acquire first words in both languages and are soon able to use these words appropriately, for example, speaking Spanish to their Spanish-speaking caregiver and English to their English-speaking grandmother (Holowaka, Brosseau-Lapré, & Pettito, 2002). In a study of a bilingual English-Portuguese infant at play with his mother and father, the child switched languages to fill in the gaps in his vocabulary. If he did not know the word for something in one language, he used the other. Similarly, his parents switched languages in order to provide words that were the best match with the child's level of understanding.

Bilingual families can use their language environment to the child's advantage, providing alternative communication strategies to improve communication and understanding (Nicoladis, 1998; Nicoladis & Secco, 2000). The richer the language environment in the two languages, the more readily children will develop bilingual competence. The more opportunities children have to hear and practice using multiple languages in everyday situations with multiple language partners, the more proficient they become (Silven & Rubinov, 2010).

Jeffry Myers/Getty Images

These young children are learning English as a second language. An early exercise is matching letters, their names, and sounds.

How do bilingual individuals prevent one language from interfering with another? Research using functional magnetic resonance imaging (fMRI) explored the process by which bilingual individuals inhibit one language while drawing on another (Rodriguez-Fornells, Rotte, Heinze, Nosselt, & Munte, 2002). Individuals who were bilingual from infancy were compared to those who were monolingual. The task involved focusing on words in one language even when words from other languages were presented. Bilinguals could identify the stimuli as words, but they did not process the words for meaning if the word was not in the language they had been instructed to pay attention to. None of the brain areas that are associated with word meaning were activated when the words in the nontarget language were displayed. The implication is that early bilingualism stimulates additional plasticity in brain organization and function to accomplish tasks that require language separation.

Regardless of which language is being spoken, the same regions of the cortex are used to produce and understand spoken language. However, when words from different languages are spoken or presented visually, an additional brain area is activated which is sensitive to monitoring and controlling the language that is in use (Crinion et al., 2006). You can think of this process as a recognition switch that toggles back and forth, alerting the person to which language they are using and suppressing interfering meaning making from other languages.

There appear to be some costs as well as benefits associated with bilingualism. Bilingual children have a smaller vocabulary overall, and in controlled experiments they are a bit slower in tasks that require thinking of words that name a picture. Benefits of bilingualism are evident in many tasks that are associated with executive control, including focusing attention, resisting distractions,

HUMAN DEVELOPMENT AND DIVERSITY (continued)

monitoring changes in stimuli, and changing strategies between tasks. Bilingualism requires paying attention to a variety of communication cues. As a result, bilingual children are especially adept at integrating multiple sources of information to understand and interpret a speaker's intentions. Bilingualism is viewed as a context that stimulates early and ongoing advantages in cognitive flexibility, selectivity, and control (Bialystok & Craik, 2010; Kovács & Mehler, 2009; Yow & Markman, 2015).

Critical Thinking Questions

1. Evaluate the following statement: "The human brain has the capacity for a great deal more language competence than is typically observed."
2. Based on the information presented here, propose a plan for parents who want to promote bilingualism in their children. How should they organize the language environment for their children?
3. Examine the potential advantages and disadvantages of bilingualism for young children.
4. Describe how the study of bilingualism contributes to the broader understanding of language development.

observed between the quality of a parent's speech toward the child and the family's socioeconomic status. Children in lower socioeconomic status families experienced less time with their parents, fewer moments of joint play, and exposure to fewer words. In these families, children were less likely to have their speech repeated or paraphrased by their parents, less likely to be asked questions, and more likely to experience prohibitions placed on their behavior.

Poverty and language development. The relationship of poverty and social class to language development is a topic of some complexity. Exposure to poverty at any point in a child's early years may have a negative impact on language development and cognitive competence. This relationship is primarily a result of disruptions in the quality of parent–child interactions (Allhusen et al., 2006). The stressors associated with poverty often create a home environment that is harsh, where parent–child interactions are infrequent, and the child has difficulty establishing a sense of meaningful connections with adults (Bradley, McKelvey, & Whiteside-Mansell, 2011). Other studies have emphasized that it is not socioeconomic status per se, but the features of parent–child interactions that are typical in lower and higher SES families that influence language development. Four features of parent–child interaction differentiate high SES and lower SES family interactions: the amount of talking, the use of a varied vocabulary, the early use of gestures to convey meaning, and the use of more complex sentences. The way parents talk to their infants and toddlers is closely related to the child's vocabulary by age 4 (Rowe & Goldin-Meadow, 2009). Within socioeconomic groups, the more children experience responsive, stimulating, and symbol-infused interactions with caregivers in the home, the further advanced their language abilities (Hirsh-Pasek et al., 2015).

The language environment can also be undermined by competing auditory events. For example, when parents have the television playing, even when it is just playing in the background, the amount of parent–child interaction is decreased. Studies have shown that when the television is playing in the background at home, toddlers' social behavior declines and their parents engage in fewer conversations with them and are less responsive (Kirkorian, Pempek, Murphy, Schmidt, & Anderson, 2009). As result of a habitual reliance on having the television playing, some parents inadvertently create environments that are disruptive to their toddler's optimal language development.

Question-asking. One component of parent–child interaction that has been studied in detail is **question-asking** by the child. Children as young as 18 months ask questions in order to gather information and accomplish other goals, such as asking permission or clarifying a situation. In one intensive study of four children, they asked an average of 107 questions an hour while engaged in conversations with adults (Chouirnard, 2007). The ability to ask questions of parents begins early in infancy and may be a universal strategy that infants use for information gathering. However, the extent to which question-asking is encouraged depends on the nature of parental responses and the way parents themselves use question-asking in daily conversation. Mothers and fathers use question-asking and requests for clarification to elicit children' speech. Frequent question-asking on the part of adults is related to toddlers' vocabulary and their own question-asking (Leech, Salo, Rowe & Cabrera, 2013; Rowland, Pine, Lieven, & Theakston, 2003).

In middle-class families, children are more likely to persist in sustained questioning where one question is followed by an answer, is followed by another question, and so on. When a child asks a lot of questions and the parent answers and gives additional information, this guides how the child builds a knowledge base and understands the world. A relationship exists between child and parent that allows the child to keep asking questions and to expect informative answers even if a question has to be asked several times in order for the parent to understand it (Harris, 2007). The ability to ask questions allows the child to gain information, trusting that it is all right to do this rather than to be rejected or rebuked with an angry response. By creating this interactive relationship around inquiry and information sharing, the child and parent create a secure base regarding access to information that offers the emotional security from which new and more exploratory forms of curiosity can grow.

Competence of partners. In learning vocabulary, children appear to be sensitive to the competence of their language partners. For example, in one study, 3- and 4-year-olds participated in an experiment where the experimenter appeared to be either knowledgeable and confident or uncertain about the name for a given toy. In the confident situation, the experimenter said things like, "I know right where my friend left her *blinket*." In the uncertain situation, the experimenter said, "I'd like to help my friend, but I don't know what a *blinket* is." Even though the children in both situations learned how the toy worked, they used the name of the toy only if the experimenter appeared confident (Sabbagh & Baldwin, 2001). The implication of this work is that by age 3, children are able to assess the expertise and confidence of the language partner before incorporating words into their vocabulary.

Scaffolding and Other Strategies for Enhancing Language Development. The process of language learning involves upward **scaffolding** and a process of mutual regulation. Scaffolding is a metaphor for providing assistance in helping someone reach a new, higher level of functioning. Verbal scaffolding refers to the variety of ways that adults help children reach a more advanced level of language competence, for example, by repeating words, offering new words, restating a child's expressions in different words, correcting a child's mistakes, or encouraging a child to say more about his or her ideas (Rodgers & Rodgers, 2004). With assistance, children can be more effective in learning vocabulary and expressing their ideas.

Sometimes a child may be misunderstood because the child's pronunciation is so discrepant from the real word (*ambiance* for *ambulance*; *tommick cake* for *stomach ache*). Adults can scaffold the child's expression by modeling the correct pronunciation. Sometimes an adult will use a word that is a little more advanced than the word the child is using, which helps the child link known vocabulary to the new word or idea. For example, "We call that kind of car that has a top that goes down a *convertible*." Scaffolding is closely related to Vygotsky's idea of the **zone of proximal development**. By interacting with a more verbally competent adult or peer, children are able to reach new levels of linguistic ability (Gregory, Kim, & Whiren, 2003; Landry, Miller-Loncar, Smith, & Swank, 2002; Rowe, 2012).

Adults do not always interact with children by encouraging the child to express ideas in a more mature form. Sometimes, adults restate or simplify their expressions to make sure they are being understood. Through frequent interactions, adults encourage language development by establishing a good balance between modifying their speech somewhat and modeling more complex, accurate speech for their children. Children respond to the scaffolding by expressing themselves in more complete sentences and by using a larger vocabulary. This reflects the idea of mutual regulation.

Adults make use of several strategies to clarify a child's meaning when the speech is unclear. One is **expansion**, or the elaboration of the child's expressions:

> CHILD: Doggie wag.
> PARENT: Yes, the dog is wagging her tail.

Another strategy is **prompting**, often in the form of a question. Here the parent urges the child to say more:

> CHILD: More crackel.
> PARENT: You want more what?

In both of these interactions, the adult is helping the child to communicate more effectively by expanding on or asking the child to elaborate on something of interest to the child. The kinds of sentences that parents use help children see how they can produce new sentences that are more grammatically correct and therefore more meaningful to others. These interactions help children express their thoughts and share their experiences with others. This has the benefit of binding the child more closely to his or her social community, while at the same time allowing others to know and understand the child more accurately (Nelson, 2010).

Pre-Literacy and the Language Environment. Socially interactive rituals, such as telling stories, playing word games, verbal joking and teasing, and reading books together, enhance language development, especially by building vocabulary and preparing children to use language comfortably in social situations. Reading aloud has been identified as an especially important language activity that helps expand a child's language skills and provides preparation for literacy (Hammer, 2001; Wood, 2002). During toddlerhood, an adult may start out by reading picture books and asking the child questions about the pictures. The adult may try to relate the picture to some event in the child's life or ask the child to tell something about the pictures. Thus, just as in scaffolding with respect to language, reading along with an experienced reader can scaffold the child's literacy skills (Leech & Rowe, 2014; Verhoeven, 2001). Over time, the child becomes more and more the storyteller, while the adult listens, encourages, and expands the tale. Some books are read aloud so often that the toddler begins to "read" them from memory or retell the story in the child's own words from the pictures. Books can become a starting point for talk about people, places, and things that can be symbolized through words, even though they are not physically present—e.g. places they have visited, people they care about, or toys and games they enjoy (Rowe, 2013).

Courtesy of Philip Newman

By reading aloud and pointing to pictures, parents and their toddlers create an environment for the development of literacy.

As children enter early school age, this type of ritualized reading activity provides a framework for the child's concept of what it means to be a reader. A common list of **pre-literacy** skills includes the following:

Vocabulary—Words and their meanings
Print motivation—Enjoying and being interested in books
Print awareness—Understanding how a book is read, top to bottom, left to right (in English)
Narrative skills—Understanding and telling stories
Letter knowledge—Naming the letters and the sounds they make
Phonological awareness—The small sounds that make up words

Certain language skills, including attention, phonological awareness, and early language comprehension, have been shown to be important predictors of reading ability in the school-age years (Overby, Trainin, Smit, Bernthal, & Nelson, 2012; Walcott, Scheemaker, & Bielski, 2010).

Reading aloud introduces the notion that printed letters make up words; stories usually have a beginning, middle, and end; and printed words and spoken words are similar in some ways. Experiences with handling books, becoming aware of the link between letters and their sounds, beginning to recognize printed words, and practicing the actions associated with reading all contribute to early reading proficiency (Hammill, 2004). Depending on the context in which children read, they may also realize that you can learn things from printed words that you cannot always know from the pictures. They discover that reading is a way to learn about the world beyond what you can know through direct experiences.

Children and parents often engage in language games that expand the child's use of words and phrases. These games are usually part of ongoing family life. They are introduced not as a separate activity, but as an extension of a related activity. The quality of toys, social games, and conversation between mothers and their infants predicts the level of the child's language development at ages 2 and 3 (Lacroix, Pomerleau, Malcuit, Seguin, & Lamarre, 2001). As an example, one mother described one of her 3½-year-old son David's spontaneous games that began to build the bridge from speech to literacy. As the game developed, the object was for David to point to road signs as he rode with his mother to nursery school and for her to read as many of the signs as possible while they were driving along. David had created this game, and his mother played along willingly (Hoffman, 1985).

> On the way to nursery school, David said, "Let's talk about signs! What does that sign say?" I answered, "Right turn signal."
>
> David proceeded with, "And what does that yellow and red shell say?"
>
> I answered him, "It says 'Shell'—that's a gasoline station."
>
> He asked, "Does it have seashells in it?"
>
> I answered, "No."
>
> We proceeded to read signs. I read the majority as he requested. However, David read "Speed Limit 35," "Bike Route," and "No Parking Any Time." When we came to "No Parking This Side of Street," he thought it was "No Parking Any Time."
>
> These were the signs that I was able to read as he requested while I was driving. They were not the only ones on the route.
>
> Speed Limit 40
> Bike Route (2 times)
> Speed Limit 35 (12 times)
> No Turn on Red (3 times)
> No Littering
> Driveway
> Watch Children
> No Parking Any Time (20 times)
> Signal Ahead (3 times)
> School Speed Limit (2 times)
> No Parking on This Side of Street (7 times)

By telling stories, reading aloud, and playing word games, children and their caregivers begin to explore a vast array of topics. Books and stories can be a starting point to talk about needs such as hunger or wanting to be comforted, or fears and frustrations. Parents and toddlers can travel along the paths of emotions such as anger, sadness, delight, pride, and shame. They talk playfully with one another, examining new objects, discussing kinship relations, and creating fantasies. Furthermore, adults and young children begin to talk about philosophical and moral questions like lying, helping, "what ifs," and the question "how would you feel if it happened to you?" As children speak from their own inner world, revealing their own point of view, parents begin to know and appreciate their children's concerns and needs in a new way. Similarly, children begin to hear and understand their family's talk in a new way. They can question what they do not understand and expand what they know through family talk.

Talk About Feelings. One area that has received special attention is the role of family conversation about feelings and its relation to a child's ability to express feelings and to identify feelings in others. Talking about feelings is closely related to experiences of validation and feelings of being understood. Consider a child who is afraid to go to sleep in the dark. Think about the difference in a child's experience between hearing a parent say "There's nothing to be afraid of," and hearing a parent say, "Tell me how you feel; let's find a way to help you feel safe." Children's use of words to refer to feelings and to describe emotions increases notably at 3 and 4 years of age. At the same time, children become more skilled at recognizing feelings in others and in understanding how a person might feel in a certain situation (Brown & Dunn, 1992). Acknowledging and talking about feelings are central to the expanding capacity for empathy and self-control. In fact, a common parenting strategy in toddlerhood is to encourage children to "use their words" instead of kicking, hitting, or biting when they feel angry. In contrast, rejecting or suppressing a child's talk about feelings are links to the emergence of a sense of shame and doubt. Toddlers who have frequent experiences of talking with their mothers when they are in distress or conflict appear to be more effective at the age of 6 in understanding the

Doug hopes that by talking with his son about his feelings, they will build a strong basis for communication in the years ahead.

point of view of others and in anticipating others' needs (Dunn, Brown, & Beardsall, 1991).

Some families have a practice of reviewing the events of the day, asking children to tell what was important to them that day and how those events made them feel. These kinds of conversations let children know that adults in the family care about their experiences and want to know more about how they are processing the events of their daily life. Children who grow up in families that are open to identifying and talking about emotions are more likely to carry on this kind of talk at later ages and to show sensitivity to others in relationships outside the family (Jenkins, Turrell, Kogushi, Lollis, & Ross, 2003).

FURTHER REFLECTION *Reflect on the words* language, thought, *and* speech. *What are the differences among these three? How are they interconnected?*

Describe the process through which language acquisition binds a child to his or her culture and social group.

Fantasy Play

OBJECTIVE 3 Explain the development of fantasy play and its importance for cognitive and social development.

Fantasy play and language are contrasting forms of representation. For language to be effective, children must use the same words and grammar as the older members of the family, discovering how to translate their thoughts into existing words and sentences. Fantasy serves almost the opposite function. In fantasy, children create characters and situations that may have a very private meaning. They play with the dolls in their doll house, arranging the baby in the crib or putting grandma doll in the rocking chair. They put little cars on the brick walkway and pretend to race them to the sidewalk. There are probably many times when children have strong feelings but lack the words to express them. They may be frustrated by their helplessness or angry at being overlooked. They can express and soothe these feelings in the world of imagination, even though the feelings may never become part of a shared conversation (Erikson, 1972). The worlds of make-believe, poetry, fairy tales, and folklore—domains we often associate with childhood—open up to toddlers as their ability for symbolization expands. Pretend play is not possible without semiotic thinking, which underlies the capacity for imagination, for allowing objects and people to take on new identities and new meaning.

The Nature of Pretend Play

During infancy, play often consists of the repetition of a motor activity. Infants delight in sucking their toes or dropping a spoon from the high chair. These are typical **sensorimotor play** activities. Toward the end of infancy, sensorimotor play includes the deliberate imitation of parental acts. Children who see their caregiver washing the dishes may enjoy climbing up on a chair and getting their hands wet, too. At first, these imitations occur only when they are stimulated by the sight of the parent's activity. As children enter toddlerhood, they begin to imitate parental activities when they are alone. A vivid mental image of an action permits them to copy what they recall instead of what they see. This is the beginning of symbolic play. Before the period of preoperational thought, children do not really pretend because they cannot let one thing stand for something else. Once the capacity for symbolic thought emerges, children become increasingly flexible in allowing an object to take on a wide variety of pretend identities.

Most 2-year-olds are able to understand the context of a pretend situation. Using pretend props, they can pretend to feed a hungry animal or give a drink to a thirsty animal. They can assign a pretend function to a substitute prop, treating a wooden block as if it were a banana or a piece of cake. And they can follow through with the consequences of a pretend situation, like pretending to wipe up pretend spilled tea with a towel. Toddlers can construct a make-believe world in which objects are assigned a pretend meaning (toy blocks can be bananas) and words are used in pretend ways ("feed the monkey a banana" is acted out by putting a toy block up to the mouth of a toy monkey) (Harris & Kavanaugh, 1993).

The Capacity for Pretense

Sometimes, adults wonder whether children can distinguish between reality and **pretense**. The line between make-believe and reality may become blurred for all of us, for example when watching television. Which televised images are pretend and which are real? Are the images and messages used to advertise products real or pretend? Is a television news story real or pretend? Are dramatic reenactments of historical events real or pretend? Are reality shows real or pretend?

In simplified situations, children as young as 2 can tell when someone is pretending and can follow the transformations in a pretend sequence (Rakoczy, Tomasello, & Striano, 2004; Walker-Andrews & Harris, 1993). For example, an investigator might tell a child that she is going to fill two bowls with cereal and then pretend to fill the bowls. The investigator then pretends to eat all of the cereal in her bowl, saying something at the end to indicate that all the cereal is gone. She then asks the child to feed a doll its cereal. Many 2-year-olds and most 3-year-olds can follow this type of scenario, selecting the bowl that is still full of pretend cereal and feeding it to the doll.

Studies about pretense lead to further speculations about what toddlers understand about someone else's mental state. For example, what do toddlers think is going on in someone else's mind as they are pretending? In judging whether someone else is pretending or not, toddlers tend to focus on the way the person is acting and the context of the situation rather than on what the person's intentions might be. Toddlers are quite accurate about judging when someone is engaging in make-believe or in a realistic activity, but they may not be able to tell you what the person is thinking about (Ganea, Lillard, & Turkheimer, 2004; Rosen, Schwebel, & Singer, 1997; Sobel, 2004).

Toddlers know the difference between what an object really is and what someone is pretending that it is (Flavell, Flavell, & Green, 1987). For example, 3-year-olds understand that a sponge is really a sponge, but they can pretend it is a boat floating in the water or a car driving along the road. Three-year-olds also understand the difference between knowing something and pretending something. If they see a rabbit, they know it is real, but they also know that they do not have to have seen a rabbit in order to imagine one. However, compared with older children, 3-year-olds are more convinced that imagination reflects reality. If they imagine something, like a fire-breathing dragon or a horse with wings, they think it may actually exist. In contrast, 4-year-olds understand that something that is imagined may not have a counterpart in reality (Woolley & Wellman, 1993). However, even though most 3- and 4-year-olds know the difference between what a real person or object can or cannot do, they continue to believe in certain imaginary characters like Santa Clause or the Tooth Fairy, who clearly defy many of these "rules" about reality.

How Fantasy Play Changes During Toddlerhood

Toddlers can direct their play in response to mental images that they have generated by themselves. At first, their symbolic play is characterized by the simple repetition of familiar activities. Pretending to sweep the floor, to be asleep, to be a dog or a cat, and to drive a car are some of the early play activities of toddlers. Fantasy play changes in four ways during toddlerhood (Lucariello, 1987; Tamis-LeMonda, Uzgiris, & Bornstein, 2012):

1. The action component becomes more complex as children integrate a sequence of actions.
2. Children's focus shifts from the self to fantasies that involve others and the creation of multiple roles.
3. The play involves the use of substitute objects, including objects children only pretend to have, and eventually the invention of complex characters and situations.
4. The play becomes more socially interactive, more organized and planned, and play leaders emerge.

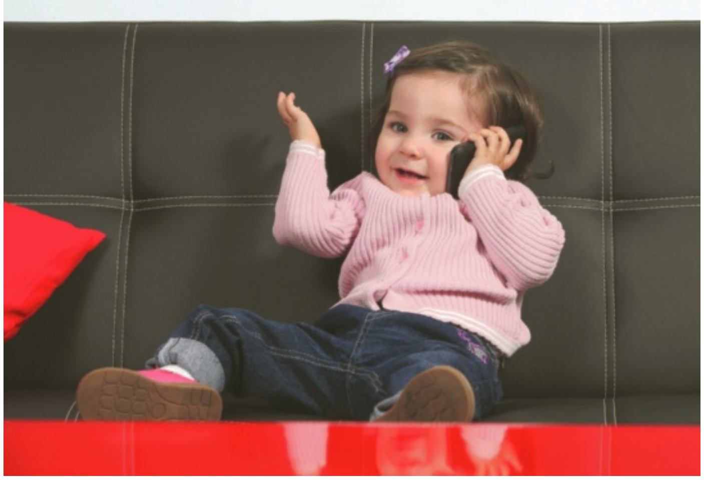
Early pretense is typically action based. Gradually, children combine a number of actions into a play sequence. From pretending to sweep the floor or take a nap, they devise strings of activities that are part of a complex play sequence. An early sequence might include changing the baby's diapers, giving the baby a bottle, singing the baby a song, and putting the baby down for a nap. In a more advanced sequence, while playing firefighter, children may pretend to be the fire truck, the hose, the ladder, the engine, the siren, the people being rescued, and the firefighters. All the elements of the situation are brought under the children's control through this fantasy enactment.

Second, children become increasingly able to include others in their play and to shift the focus of the play from the self to the others (Howes, 1987; Howes, Unger, & Seidner, 1989). One can see a distinction here between solitary pretense, social play, and **social pretend play**. Children engaged in solitary pretense are involved in their own fantasy activities, such as pretending that they are driving a car or giving a baby a bath. Children engaged in social play join with other children in some activity.

In social pretend play, children have to coordinate their pretense. Play companions' interactions are interdependent. What one child does influences the others. They establish a fantasy structure, take roles, agree on the make-believe meaning of props, and solve pretend problems. As you may guess, participation in social pretend play and creativity are closely related in toddlerhood. The fact that 3- and 4-year-olds can participate in this type of coordinated fantasy play is remarkable, especially given their very limited use of language to establish and sustain coordination (Mottweiler & Taylor, 2014; Rubin, Bukowski, & Parker, 2006).

Third, fantasy play changes as children become more flexible in their use of substitute objects in their play. Fantasy play begins in the areas closest to children's daily experience. They use real objects or play versions of those objects as props in their pretense. For example, they pick up a toy telephone and pretend to call Grandma, or they pretend to have a picnic with toy cups and plates and plastic foods. But as they develop their fantasy skills, these props are no longer essential. Children can create novel uses for common objects like using a bowl for a hat or a scarf for a baby blanket. Sometimes they pretend to have an object when they have nothing, gesturing as if they have a gun or a sword. Despite these remarkably inventive capacities to impose meaning on neutral objects, children's toys have become increasingly more realistic, reflecting the nature of modern technology. Whereas experts in early childhood education continue to recommend the use of flexible, open-ended play materials for young children like blocks or clay, toy makers appear to be enthusiastic about producing realistic play materials like plastic cell phones, kitchens, computers, and carpenter's tools.

Play moves away from common daily experiences to invented worlds, which are often based on stories, television programs, movies, or purely imagined characters and situations. Cultural, religious, and entertainment heroes, heroines, and stories filtered through the cognitive interpretations of young children become the content for pretense. Three-year-olds may generate negative as well as positive imaginary images, including fears about supernatural creatures, witches, ghosts, zombies, and monsters. Children may take the roles of characters with extraordinary powers. They may pretend to fly, become invisible, or transform themselves into other shapes with the aid of a few secret words or gestures. Their identification with a particular fantasy hero or heroine may last for days or even weeks as they involve the characters of the story in a variety of fantasy situations.



Antonio Guillem/Shutterstock.com

The cell phone has become a common resource for pretense as well as for real communication.

Fourth, fantasy play becomes more socially interactive. It becomes more planned and organized as children try to coordinate their pretend play with others. There are new discoveries about what makes pretend play most fun, and a desire to make sure that those components are included in the play. In a preschool or child care group, certain children are likely to take the lead in organizing the direction of fantasy play. They may set the play in motion or give it direction by suggesting the use of certain props, assigning roles, or working out the context of the play. Social skill development and social pretense influence each other. The more socially skilled children are likely to take a leadership role in the coordination of group pretense; as other children participate in these coordinated play scenarios, their social competence is also likely to improve (Li, Hestenes, & Wang, 2016). In the example below, a child demonstrates this kind of leadership:

> STUART (climbing up on a tractor tire): This will be our shark ship, OK? Get on quick, Jeremy! The sharks will eat you!
>
> JEREMY: No! This is my police helicopter!
>
> STUART: Well, OK. We're police. But we need to chase the sharks, OK? I see the sharks way down there! Come on!
>
> JEREMY: OK. Let's get 'em! (They both make helicopter noises and swat at make-believe sharks with plastic garden tools.) (Trawick-Smith, 1988, p. 53)

Some theorists distinguish symbolic role-playing from games with rules, implying that the latter are guided by a formal set of mental operations that constrain play, whereas the former is open and flexible. However, it is clear that pretend play operates within a rule-bound structure (Harris & Kavanaugh, 1993; Vygotsky, 1978c). In order to coordinate **symbolic play** with a partner, children have to come to some mutual understanding about the situation, props, characters, and plot. The players have to limit their behavior in ways that conform to the unspoken or latent rules of the pretense. For example, if the children decide that certain leaves are the pretend food, then no one can use the leaves as bricks to build a house or as hats. If one player is supposed to be the mommy, that player has to act like the mommy and not like the baby. In games with rules, the rules are more readily spelled out, but in both types of play, part of what makes it fun is to function within the boundaries of certain kinds of constraints.

Dramatic role-playing, in which a child takes on the role of another person or creates a fantasy situation, increases steadily from the ages of 3 through 5. By the age of 6, however, children become involved in games with rules. They may use their fantasy skills during play by making up new games or new rules rather than by engaging in pretend play. If one is looking for the experts in diversified, elaborated fantasy, observe 4- and 5-year-olds.

Theoretical Views about the Contributions of Fantasy Play to Development

Fantasy play is not simply a diversion. Children use fantasy to experiment with and understand their social and physical environments and to expand their thinking (Pellegrini & Bjorklund, 2004). Theoretical views of the importance and value of fantasy play vary widely. Here we consider how Piaget, Vygotsky, and Erikson understood the role of fantasy play.

Piaget (1962) emphasized the assimilative value of play. He believed that through fantasy and symbolic play, children are able to make meaning of experiences and events that are beyond their full comprehension. Fantasy play is a private world to which the rules of social convention and the logic of the physical world do not necessarily apply. From this perspective, fantasy play frees the child from the immediacy of reality, permitting mental manipulations and modifications of objects and events. One cognitive benefit of fantasy play is the opportunity to engage in role reversal, taking turns playing the various characters, which helps to advance perspective taking among play companions.

Vygotsky (1978c) saw fantasy play quite differently.

> Play creates a zone of proximal development of the child. In play a child always behaves beyond his average age, above his daily behavior; in play it is as though he were a head taller than himself. As in the focus of a magnifying glass, play contains all developmental tendencies in a condensed form and is itself a major source of development. (p. 102)

Vygotsky used the term zone of proximal development to refer to the distance between the actual level of a child's performance and the potential level that a child is capable of reaching with help from a more skilled peer or adult. Normally adults—especially parents and teachers—and more advanced peers promote development by engaging children in activities and problem-solving tasks that draw children into their zone of proximal development—the new directions along which their capacities are moving. However, in play, Vygotsky saw a cognitive process that captures a foreshadowing of the child's next higher level of functioning.

In pretense, children address areas where they do not yet feel competent in their lives and try to act as if they were competent. They set rules for their performance, and commit themselves to function according to them. So if a child is pretending to be a good mother, she brings forward all the ideas she has about how to be a good mother and applies them to the pretend situation.

Similarly, if a child is pretending to be a superhero, she imposes all the rules of power, goodness, and helpfulness that she knows of and tries to limit her actions to those rules. Vygotsky regarded fantasy play as a window into the areas of competence that the child is striving to master but are still out of reach.

Erikson (1972) considered fantasy play vital in promoting personality and social development. He valued play as a mechanism for dramatizing the psychological conflicts that children are struggling with, such as angry feelings toward their siblings or parents, or jealousy over a friend's new toys. According to Erikson, the play often not only represents the problem but also offers a solution so that children experience some new sense of resolution and a reduction in the tension associated with the conflict. For example, Leslie is frustrated because her older brother, Harold, got to go with his dad to the movies, and she had to stay home with a babysitter. In play, Leslie goes to the movies, and her doll has to stay home. Symbolic play provides a certain flexibility or leeway in structuring the situation and, at the same time, imposes some limits so that children may experience a new mastery of issues that are perplexing or overwhelming in real life. One way that children use pretend play to explore relationship issues and mastery of puzzling questions involves creating an imaginary companion to serve as a play partner (see the **Applying Research and Theory to Life** box Imaginary Companions).

Pretend play is a form of representational thought—a way that children experiment with the relationships of objects and social roles. For children who have some forms of language delay, observations of their pretense provide insight into their cognitive capacities. Research suggests that high-quality pretend play actually fosters cognitive, emotional, and social development (Bergen, 2002). Children who have well-developed pretending skills tend to be well liked by their peers and viewed as leaders. This may be linked to their advanced communication skills, their greater ability to take the point of view of others, and their ability to reason about social situations. Children who have been encouraged in a playful, imaginative approach to the manipulation and exploration of materials and objects through fantasy show more complex language use and more flexible approaches to problem solving. Children who have frequent opportunities for pretend play—especially with a more experienced play partner—are better able to express their feelings, show higher levels of empathy, and are more aware of their emotional states (Galyer & Evans, 2001; Lindsey & Colwell, 2003).

Pretend play emerges through the coordination of cognitive, motor, and emotional development. At the same time, pretense appears to contribute to the further maturation of these domains. In the context of the preschool, pretense is not the sole contributor to advances in learning, but it contributes to a joyful environment in which new learning can occur. It supports social interactions with peers and adults, and offers a comfortable context in which children can express new ideas, integrate information from life events, and arrive at new insights about important questions they face in daily life (Hopkins, Dore, & Lillard, 2015; Lillard et al., 2013; Snow, 2016).

Fantasy play is essential for the full social, intellectual, and emotional development of young children. Some parents and teachers want to define a young child's cognitive growth in terms of the acquisition of words and concepts that seem relevant to the real world. They emphasize the importance of learning numbers and letters, memorizing facts, and learning to read. However, research on cognitive development suggests that gains in the capacity for symbolic play provide essential foundations for subsequent intellectual abilities, such as abstract reasoning, creativity, and inventive problem solving. What is more, by integrating pretense as a teaching/learning strategy, opportunities for play enhance children's motivation to learn, improve their ability to sustain their attention, and provide practice in using new concepts in innovative contexts (Singer, Golinkoff, & Hirsh-Pasek, 2006).

The Role of Play Companions

Cognitive developmental theory emphasizes representational thought and symbolic play as the natural outcomes of cognitive maturation during toddlerhood. However, the quality of that play as well as its content depend in part on the behavior of a child's **play companions**. Consider the following incident:

> In a university preschool where college students were having their first supervised experience as teachers of young children, a child of 3 made a bid for some pretend play with a student teacher. The child picked up the toy telephone and made ringing noises. The student teacher picked up another phone and said, "Hello." The child asked, "Is Milly there?" The student teacher said, "No" and hung up the phone. Rather than extending the pretense into a more elaborate social pretend situation by saying something like "Who is calling?" or pretending to put Milly on the phone, the student teacher brought the scenario to a close.

As play companions, parents, siblings, peers, and child care professionals can significantly enrich a child's fantasy play. Play companions can elaborate a child's capacity for fantasy, legitimize fantasy play, and help the child explore new domains of fantasy. When mothers are available as play companions, the symbolic play of their 2-year-old children is more complex and lasts longer (Slade, 1987; Tamis-LeMonda, Uzgiris, & Bornstein, 2012). Parents may engage in pretend actions with their toddlers, like pretend eating, caring for the doll baby, or creating the pretend town where the bus or the train travels along, gathering up passengers. As a toddler's capacity for pretense improves, parents' active engagement in the pretense may change, possibly helping to set up the resources for play or talking about the play rather than joining in the play (Ban & Uchiyama, 2015).

When adults are trained to engage in and encourage pretend play, the toddlers show a higher level of ability to coordinate their responses with those of the adults. Toddlers become increasingly skillful in directing an adult's behavior and negotiating changes in kinds of play. Early and frequent opportunities to pretend with older siblings, peers, and parents contribute to a young child's ability to understand other people's feelings and beliefs. As toddlers experiment with pretend roles, construct fantasy situations, and manipulate objects with a play companion, they establish new channels of shared meaning, thus fostering a new degree of awareness about self and others. Frequent opportunities for social pretend play with peers is associated with advances in early learning (Bulotsky-Shearer et al., 2012).

APPLYING THEORY AND RESEARCH TO LIFE

Imaginary Companions

Probably the most sophisticated form of symbolic play is the creation of an **imaginary companion**. An imaginary friend, which may be an animal, a child, or some other creature, springs complete in concept from the mind of the child. It occupies space. It has its own personality, which is consistent from day to day. It has its own likes and dislikes, which are not necessarily the same as those of its creator. Although not all children who have imaginary companions will disclose this information to adults, some studies have shown that as many as 65 percent of young children have imaginary companions, and some children have more than one (Singer & Singer, 1990).

In one study in the United Kingdom, 1,800 children were asked about past or present experience with imaginary companions. Roughly 46 percent said they had one (Pearson et al., 2001). When parents were surveyed about their children, those with imaginary companions were more likely to be firstborn or only children, were judged by parents to be very imaginative in other aspects of their play, and to enjoy magical or fantasy play as compared to other forms of play. Children who have imaginary companions also report a more vivid imagery when daydreaming or engaging in pretend play and more mythical creatures in their dreams (Bouldin, 2006).

Children who have imaginary companions tend to have more extensive language competence that is observable in conversations with their invisible friend (Bouldin & Pratt, 1999; Gleason, Sebanc, & Hartup, 2003). They are also more likely to engage in covert private speech (Davis, Meins, & Fernyhough, 2013). One by-product of having ongoing conversations with an imaginary companion and telling others about one's adventures with an imaginary companion is that children gain practice in storytelling. As a result, children who have imaginary companions also have advanced abilities to produce verbal narratives as evidenced in the way they retell stories, explain past situations to others, and expand on their experiences in social conversations (Trifoni & Reese, 2009). Another by-product is a greater self-knowledge. Compared to children who do not have an imaginary companion, those who do are more likely to understand that they have unobservable thoughts, feelings, and dreams of which adults are unaware (Davis, Meins, & Fernyhough, 2011).

Several functions may be served by an imaginary friend: It takes the place of other children when there are none around; it serves as a play companion for pretend play; it serves as a confidant for children's private expression; it helps to overcome boredom and loneliness; it provides support when children face difficult situations; and it is often involved in their efforts to differentiate between right and wrong (Majors, 2013; Taylor & Mannering, 2006). Children can distinguish the social relationship they have with their imaginary companion from the relationships they have with parents, siblings, and best friends. Imaginary companions and real friends are viewed as similar in many ways, but children are more likely to comfort and nurture their imaginary friend than their real friend (Gleason, 2002).

Critical Thinking Questions

1. Explain how imaginary friends might get created. What experiences, ideas, or mental states might be necessary in order for an imaginary companion to be invented?
2. Imagine that you are 3 or 4 years old. What type of imaginary companion would you create for yourself? Why? Could you have an imaginary companion now? Is there an equivalent of an imaginary companion in the lives of adults? What functions do they fill?
3. Design a study to explore the similarities and differences between imaginary friends and real friends. What approach might you take to investigate this question? What would be some challenges you would need to overcome in order to pursue this problem?
4. Do you think that having an imaginary friend in childhood has any relationship to creativity and imagination in adulthood? How could you find out about this?

For many children, the child care setting is where they interact with play companions. When children are with the same group of teachers and classmates over time, their play becomes more complex. Because toddlers rely so heavily on imitation and nonverbal signals to initiate and develop their social pretend play, the more time they have together, the more complex their fantasy play will be. Children who have had many changes in their child care arrangements, or who are in settings where there is frequent staff or student turnover are less likely to engage in complex social pretense (Eckerman & Didow, 1996; Hirsh-Pasek, Golinkoff, Berk, & Singer, 2009).

The importance of pretense and the way pretend play is nurtured depends in part on the meaning it is given in one's culture. For example, among the Ijaw of Nigeria, children under 5 are thought to have a special link with the female creator spirit. Adults may watch a young child playing alone, interacting with imaginary companions by giving out pretend food, or speaking to them in a happy tone. Rather than dismissing this activity as child's play, the adults believe that the child is interacting with the spirit world and will take care not to disrupt the activity. An Ijaw woman who wants to become pregnant might try to appeal to a small child, hoping that if she is kind to the child, the child will use this special link to the spirit world to help bring about the pregnancy (Valsiner, 2000). In most U.S. families, the idea that children have imaginary companions may be considered quaint or amusing. But in some cultures, the ability of children to interact with an invented world is viewed with great respect. Among scholars of child development, this ability to create and sustain an imaginary companion is considered evidence of advanced symbolic representation, an emerging sense of self, and a strategy for achieving new levels of self-control.

FURTHER REFLECTION *Describe how the capacity for pretense contributes to development in childhood. Evaluate the value contemporary U.S. society places on fantasy play in childhood; in adulthood. What would you expect to observe in a culture that places great importance on individuals' imaginative play?*

Self-Control

OBJECTIVE 4 Examine the factors that contribute to the development of self-control, including impulse management and goal attainment.

Do you ever find that you hit the snooze button and roll over for 10 more minutes of sleep even when you know you should get out of bed? Does your mind wander when you need to be paying attention? Do you go for that extra helping of cake when you are trying to lose 5 pounds? These are just a few examples of lapses in self-control. Self-control is frequently noted as a marker of maturity. The ability to control impulses, direct action toward a goal, express and inhibit the expression of emotions, and resist temptation are all evidence of this capacity (Myrseth & Fishbach, 2009). Over time, self-control becomes a foundation for moral behavior.

In toddlerhood, rapid changes in language, motor skills, and purposeful behavior come together as children strive to become meaningfully integrated into their families and communities. At the same time, toddlers encounter new demands to limit their actions, suppress their strong emotions, and modify their requests in coordination with the needs of others. For toddlers, **self-control** is observed in the ability to comply with a request, modify behavior according to the situation, initiate or postpone action, and behave in a socially acceptable way without having to be guided or directed by someone else (Brownell & Kopp, 2007a). In the following sections we consider two components of self-control: (1) control of impulses—a form of self-control directed inward toward managing one's emotional states and drives (see the **Applying Theory and Research to Life** box for a discussion of the expression and control of angry feelings) and (2) self-directed goal attainment—a form of self-control directed outward in action toward mastery of the environment (Carver & Scheer, 2016).

Control of Impulses

Early in infancy, self-control is usually understood as the infant's ability to prevent the disorganization of behavior brought on by overstimulation and to recover from emotional distress. Babies have a variety of internal regulating strategies (Brownell & Kopp, 2007b). For example, by sucking or rocking, babies can soothe themselves. They can also resist overstimulation by turning away from the source of stimulation, crying, or going to sleep.

During toddlerhood, children improve their ability to modify and control their impulses. The case of Colin illustrates how toddlers may fail to control their impulses. Sometimes, they simply cannot interrupt an ongoing action, even one they know is inappropriate. Colin, age 2 years 9 months, is just starting preschool:

> In his relations with children, Colin progressed quickly from a quiet, friendly, watching relationship on the first few days to actively hugging the other children. The hugging seemed to be in an excess of friendliness and was only mildly aggressive. Having started hugging, he didn't know how to stop, and usually just held on until he pulled the child down to the floor. This was followed very closely by hair pulling. He didn't pull viciously, but still held on long enough to get a good resistance from the child. He grabbed toys from others. When stopped by an adult from any of these acts, he was very responsive to reason, would say, smiling, "I won't do it any more," would tear around the room in disorganized activity, and then return to hugging or pulling hair. (Murphy, 1956, pp. 11–12)

From ages 2 to 4, most children are increasingly able to modify and control their impulses and withstand delays in gratification. They also become more willing to modify their behavior because they do not want to cause distress to others. The ability to regulate or restrain behavior is a product of changing cognitive, social, and emotional competencies. As executive functions in the prefrontal cortex mature, toddlers are better able to focus their attention and slow their behavioral reactions. Children become increasingly sensitive to the negative consequences of impulsive acts. At the same time, they develop new strategies to help manage feelings of frustration, such as distracting themselves and redirecting their attention to some alternative activity or toy, creating a pretend scenario in which they soothe themselves through conversation with a fantasy character, using some physical soothing or comforting strategy like thumb sucking or cuddling with a blanket, and seeking comfort or distraction from a parent or play companion (Berger, 2011).

It takes a lot of self- control to cope with her baby sister's screaming. Annie holds her ears and stays calm, hoping someone will come soon to soothe her sister or at least get her out of the bed.

APPLYING THEORY AND RESEARCH TO LIFE

The Expression and Control of Angry Feelings

The expression of anger, which is important to the child's development of a sense of autonomy, typically generates tension between parents and children. Toddlers get angry for many reasons, including inability to perform a task, parental restrictions on behavior, and peer or sibling rivalry. As toddlers become increasingly involved in directing the outcomes of their activities, they get angry when someone interrupts them or offers unrequested assistance. Toddlers are likely to get angry when they are tired, or when forced to make a transition from something they are enjoying to something someone else wants them to do.

Studies involving observational and mothers' reports provide evidence that during the second year of life, children begin to use physical aggression toward other children. This is especially likely when children want something that another child has or in retaliation if a child hits them (Baillargeon et al., 2007). The most common forms of physical aggression at this age are kicking, biting, pushing, and hitting. Between ages 2 and 5, the frequency of physical aggression declines as children develop effective strategies for self-control.

In addition to physical aggression, some children use relational aggression to harm others. In toddlerhood, **relational aggression** involves behaviors that result in social exclusion by refusing to let a child join in a play activity, making fun of another child, telling another child that you don't want to be his or her friend, or failing to invite one child to a party when many other children in the class or group are invited (Murray-Close & Ostrov, 2009).

Some children are temperamentally more aggressive than others. Although occasional acts of aggression are not uncommon among toddlers, only a small percentage of toddlers are frequently aggressive and irritable (Paulussen-Hoogeboom, Stams, Hermanns, & Peetsma, 2007; Tremblay et al., 2004). These children are characterized by negative emotionality and difficulties in emotion regulation. They are more frequently in a negative mood, get angry easily, have a highly intense negative reaction to any type of limit-setting, and when upset, have a hard time recovering or returning to a calm state (Calkins & Dedmon, 2000).

Children rely on their parents as models for learning how to express and control anger. The times when parents are angry are very important. Children learn as much or more about the expression of anger from watching their parents when they are angry as they do from verbal explanations or punishment (Bandura, 1977). Children are sensitive to angry expressions directed toward them through both verbal and nonverbal behavior. In some parent–child dyads, anger is a dominant theme in the parenting interactions. Parents who are angry and abusive toward their children provide a model for the imitation of angry behavior. Children are also sensitive to anger between their parents, even when it is not directed at them. Parents' hostility to each other, expressed through quarrels, sarcasm, or physical abuse, increases children's sensitivity to anger and is closely related to disturbances in development (Kochanska, Aksan, & Joy, 2007).

Exposure to parental aggression not only provides a model for the expression of aggression but also creates a stressful environment that is accompanied by physiological reactions, especially activation of the hypothalamic-pituitary-adrenocortical (HPA) axis and the autonomic nervous system (ANS). It is probable that repeated engagement of these stress-response systems results in conflict sensitization, a heightened reaction to conflict that can be experienced as "arousal, anger, anxiety, or the desire to avoid confrontation" (Margolin, Ramos, Timmons, Miller, & Han, 2016, p. 16). For many children, the punitive or hostile family environment creates a lower threshold to the perception of threat and a heightened physiological reaction, which they are less able to regulate. A combination of a lack of parental supports that help children recover from stressors and the dysregulation of internal physiological responses create a pattern of reactions to conflict that are carried forward into later aggressive behaviors, especially in relationships with peers, love relationships, and parenting (Berlin, Appleyard, & Dodge, 2011; Margolin, Ramos, Timmons, Miller, & Han, 2016).

Not all parenting efforts are directed at inhibiting the expression of anger. In an ethnographic study of the socialization of anger and aggression, three 2-year-old girls and their mothers from a working-class neighborhood of Baltimore were studied in detail. The mothers considered assertiveness and self-defense essential to survival in their neighborhood. Along with socialization strategies that focused on controlling inappropriate aggression, the mothers found many ways to model aggressiveness toward others and to reward certain displays of toughness and assertiveness in the girls' behavior (Miller & Sperry, 1987).

Children who can express anger without losing control make tremendous gains in the development of autonomy. Anger or conflict with parents gives toddlers evidence that they are indeed separate from their parents and that this separateness is legitimate. Children who are severely punished or ridiculed for their anger are left in a state of doubt. They see models for the expression of anger in the way their parents respond to them, and yet they are told that anger is not appropriate for them. The goal in the socialization of angry feelings is to help children find legitimate expressions of anger without hurting themselves or others.

Recall from the opening case how Rena used her tone of voice, physical comfort, and giving Harrison a few choices to help him manage his anger in the classroom. In some preschools there is a "peace table." Typically the peace table has an object that represents peacefulness. The child who is speaking holds the object, and then gives it over to the other child to have a turn to speak. The peace table slows things down so children can step away from the conflict, take time to say what is bothering them, and listen to each other. When children

APPLYING THEORY AND RESEARCH TO LIFE (continued)

are having angry conflicts, they might be reminded to try using the peace table where they can talk about the problem and try to resolve the conflict.

Different strategies can help young children regulate or reduce the intensity of their anger. These strategies have to be coordinated with the child's temperament and the ecological context in which the anger takes place (Brinkmeyer & Eyberg, 2003; Kochanska, Aksan, & Joy, 2007; Thompson, 1990).

- Increase a child's experiences of positive, responsive interactions with caregivers through playfulness, conversations, positive tone of voice, or comforting touch. This has been found to increase a child's sense of security and willingness to cooperate with parental requests.
- Provide a brief time-out in a nearby quiet area to help children return to a calm state.
- Arouse feelings that are incompatible with anger, especially empathy for a possible target for one's aggressive impulses.
- Minimize exposure to stimuli that arouse aggressive or fearful impulses.
- Explain the consequences of a child's aggressive actions for others.
- Suggest ideas about acceptable ways to express or release angry feelings such as drawing, going for a run or a bicycle ride, or digging in the yard.
- Model strategies for nonaggressive responses to frustration and conflict. Use peaceful language and talk about peaceful ways of resolving conflict.

Critical Thinking Questions

1. How does the expression of anger help a toddler achieve autonomy? What functions might the expression of anger serve in later stages of development?
2. Why is anger both difficult to express and difficult to control once it is expressed?
3. How does the expression of angry feelings fit in with your ideas about optimal childrearing strategies and socialization goals?
4. There are temperamental differences in the tendency to get angry, and these differences might be accentuated by certain parenting practices. Imagine that you are advising parents about how to respond to their child's anger. What different advice would you give if you thought that the child was especially anger-prone as compared to a child who was especially fearful and inhibited?
5. What might be some gender differences in the experiences of anger and in societal preferences for the expression and control of anger? Do you think there is a biological basis for gender differences in aggressive behavior? What evidence would you need to support your conclusion?

Increasing Sensitivity to the Distress of Others

Toddlers can observe and empathize with distress expressed in others, both children and adults. Moreover, they begin to understand when they have been the cause of someone else's distress (Hay & Cook, 2007; Hoffman, 2007; Zahn-Waxler et al., 1992; Zahn-Waxler, Robinson, & Emde, 1992). Often, the socialization environment helps to focus toddlers' attention on these instances when parents or teachers point out their actions and the consequences. The following observation from a study of family interaction shows how a conversation about negative consequences and a child's concern over his mother's distress contributed to the self-regulation of impulses:

> Danny is 33 months old. He and his mother are at the sink washing dishes. Danny blows a handful of suds at his mother and some gets in her eyes. Danny is laughing at this new game.
>
> Mother: No! Nuh uh, Danny. Danny, you got it in my eye. (mild negative affect)
>
> Danny stops laughing.
>
> Mother: Don't do that in my eye, OK? It hurts to get soap in your eye.
>
> Danny: (very serious) I won't. (Brown & Dunn, 1992, pp. 347–348)

Parents and teachers play an important role in socializing toddlers toward concern about the impact of their behavior on others. Through their talk about feelings and their explanations about what causes happy, sad, or angry feelings, they alert toddlers to the possibility that their actions can have positive and negative consequences for others. Language skills, feelings of guilt and the desire to make reparation, and cognitive capacities including the ability to focus attention and inhibit or modify their actions contribute to toddlers' ability to regulate their behavior in order to consider the other person (Brownell & Kopp, 2007b; Colasante, Zuffiano, Bae, & Malti, 2014; Rhee et al., 2013).

Discipline Strategies and Impulse Control. In toddlerhood, the immediate aim of discipline is to achieve compliance (Edwards & Liu, 2012; Kochanska, Aksan, & Koenig, 1995). A parent typically wants children to stop doing something ("Don't touch those figurines; they might break") or to do something ("Help me put the toys away now; it's time to go to bed"). If the child complies, a parent might respond positively by smiling, patting the child or giving a hug, or complimenting the child for being good, helpful, or obedient. If the child does not comply, a parent may try some form of distraction or offer some choice ("You can help clean up the toys or help me fold the laundry"). Sometimes, when the child is doing something else, a parent may give a "five minute warning" ("In five minutes it will be time to wash up and get ready for bed"). But if compliance is not forthcoming, some type of discipline is likely to ensue. Many parents use a combination of techniques including verbal instruction, verbal warnings, time-out, and praise to encourage compliance (Kremer, Smith, & Lawrence, 2010).

Discipline practices have been described in three general categories (Hoffman, 1977; 2000):

1. **Power assertion:** Physical punishment, shouting, attempts to physically move a child or inhibit behavior, taking away privileges or resources, or threatening any of these things. Any action that takes advantage of a parent's greater power in the parent–child relationship, whether it is due to physical size, control of resources, or threats of violence, can be interpreted as power assertion.
2. **Love withdrawal:** Expressing anger, disappointment, or disapproval; refusing to communicate; walking out or turning away. Love withdrawal implies that a parent's love is conditional upon a child's good behavior. It can be given or taken away.
3. **Inductions:** Explaining why the behavior was wrong; pointing out the consequences of the behavior to others; redirecting the behavior by appealing to the child's sense of mastery, fair play, or love of another person. Inductions build on the child's cognitive understanding of the situation and their empathy for others.

In addition to these three general categories of discipline techniques, parental warmth, modeling desired behaviors, and praise of acceptable or desired behaviors contribute to the development of internal control (Callahan, Stevens, & Eyberg, 2010; Maccoby, 1992). In order to correct their behavior, children must know what acts are considered appropriate as well as how to inhibit their inappropriate acts. Modeling and reinforcement aid children in directing their behavior; discipline serves to inhibit or redirect it.

The manner in which discipline is carried out over time is associated with child outcomes, especially increases in self-regulation, compliance, prosocial behavior, and the eventual internalization of moral standards; or increases in noncompliance, aggressiveness, and low levels of moral reasoning. On the one hand, when parents make greater use of inductions, their children have fewer problems managing their angry feelings or harming others. On the other hand, when children behave in a very angry, aggressive way, their parents are increasingly likely to use power-assertive tactics to limit or control the child's behavior (Choe, Olson, & Sameroff, 2013).

Three features of the approach to discipline appear to be important (O'Leary, 1995):

1. The discipline should be immediate or as close in time to the situation as possible. Laxness in discipline, such as laughing at an undesirable behavior, waiting too long to respond, reprimanding the child sometimes but not at other times for the same misconduct, or inadvertently rewarding a child for misconduct are all practices that are likely to increase rather than decrease the undesired behavior.
2. The discipline for a toddler should be brief. It is important to make sure that the toddler understands what the misbehavior was and why it was wrong, but the explanation should be concise and presented at the toddler's level of understanding. Punishment involving love withdrawal is especially likely to be carried on too long. The parent should make sure the toddler knows when the punishment is over and not let the child spend hours thinking the parent is still angry.
3. The discipline should be appropriately firm, but not overreactive. The response to noncompliance should be coordinated with the child's behavior, focusing on expressing concern for the harm that was done, engaging the child in talking about how to repair the situation, and setting the stage for what the child might do next (Edwards & Liu, 2012). Practices that are intensely harsh, abusive, or cruel, whether they involve physical, verbal, or emotional intensity, are associated with increases in problem behaviors. Infrequent use of power-assertive punishment in an overall context of a warm, nurturing relationship may be effective in fostering compliance. However, intense and frequent harsh punishment is associated with a variety of maladaptive consequences for children including problems in emotional regulation and poor inhibitory control (Hallquist, Hipwell, & Steppe, 2015; Lucassen et al., 2015; Repetti, Taylor, & Seeman, 2002; Weiss, Dodge, Bates, & Petit, 1992).

Where Does Time-Out Fit as a Discipline Strategy?

Time-out is a widely used strategy to reduce disruptive or noncompliant behavior among young children. Its proper and sensible use is recommended in many programs established to support parenting, especially parenting young children and children who have conduct problems. **Time-out** is generally defined as a specific period of time when a child is removed from opportunities for desired reinforcements such as social interaction, play, or parental attention. There are many variations in the implementation of time-out. The Clark family was very enthusiastic about hockey. They referred to time out as time in the "penalty box." This renaming allowed the family to help their child interpret time out as part of a system of rules about behavior: When the rules are broken, there is a penalty—it has a limited duration and then you can rejoin the group.

As a discipline strategy, we see time out as a combination of power assertion and love withdrawal. The parent/caregiver calmly but insistently directs the child to a nonreinforcing environment—possibly a nearby chair, a specific location in the room, or another room. During the specific period of time-out the child is separated from the reinforcing attention and affection of the parent/caregiver. The more interesting and loving the "time-in" environment is, the more salient the time-out experience will be, and the less often it will need to be invoked. However, the proper use of time-out is in coordination with other discipline strategies, especially explanations about why the behavior was unacceptable, and why the child is being sent to "time-out." The technique has been found effective when the parent is able to remain calm, the time-out period is brief, the reunion re-establishes warmth and communication, and the technique is used in combination with other positive guidance strategies (Morawska & Sanders, 2011).

Harsh Discipline. Harsh discipline, including physical punishment like spanking or use of the strap, yelling, angry and prolonged time-outs, and threatening violence are all associated with negative outcomes. In a national survey of U.S. parents, 22 percent say they often raise their voice or yell at their kids; 17 percent say they use spanking as a form of discipline at least some of the time (Pew Research Center, 2015). Children who are exposed to **harsh discipline** are more likely to show difficulties in aggressive behaviors, noncompliance, difficulties in emotion regulation, and anxiety associated with perceptions of the world as a fearful, threatening place. Thinking back to the attachment system, it is especially disruptive for young children to experience fear of their primary caregiver, since the primary caregiver is supposed to be the source of comfort and security under conditions of threat, not the source of threat itself. The relationship of harsh discipline to emotional and behavior problems has been observed across social and economic groups, and in cross-national comparisons (Olson et al., 2011; Runyan et al., 2010).

Economic hardship produces emotional distress among parents, which is likely to result in harsh, neglectful, or erratic parent–child interactions (McLoyd, 1990). Mothers living in poverty are more likely than more affluent mothers to use power assertion and physical punishment as a form of discipline. Studies of the relationship of poverty to parenting practices and children's mental health have found that the amount of spanking parents use is directly related to the family's current level of poverty. Under conditions of extreme poverty, family conflict and parental stress are most likely to undermine a parent's coping strategies and result in the use of harsh discipline (Pereira, Negrão, Soares, & Mesman, 2015). The conditions of poverty that contribute to harsh parenting are moderated by parental characteristics, such as poor executive functioning, depression, and exposure to harsh parenting as a child; child characteristics such as oppositional behavior, disability, or poor emotional regulation; and neighborhood stressors such as high crime rates; unsafe, chaotic streets; or hazardous housing (Barajas-Gonzalez & Brooks-Gunn, 2014; Deater-Deckard, Wang, Chen, & Bell, 2012; Norlin, Axberg, & Broberg, 2014).

Regardless of their socioeconomic level, the more parents use spanking and harsh discipline—especially when it is used without accompanying emotional support or warmth—the more likely their children are to show signs of emotional distress (depression, fearfulness, and crying) and externally directed behaviors such as arguing, disobedience, destructiveness, and impulsiveness (Conger et al., 2002; McLeod & Shanahan, 1993; McLoyd & Smith, 2002). Infants and toddlers whose home environments are characterized by high levels of conflict, anger, and aggression and who are targets of harsh, cold, unsupportive, and neglectful parenting are at great risk for disruptions in self-regulation. Early experiences of abuse produce repeated physiological responses of fear, anxiety, and stress. Over time, these stress responses result in greater fearfulness, dysregulation of the natural systems that are helpful in calming and controlling emotions, and difficulty regulating anxiety and depression. Toddlers have fewer chances to observe or model effective strategies for handling conflict and are more likely to behave in aggressive ways with peers. The lack of social competence that is caused by harsh parenting is likely to result in peer rejection, weak social relationship skills, and low levels of social integration (Repetti, Taylor, & Seeman, 2002; Repetti, Robles, & Reynolds, 2011).

Individual Differences in the Ability to Control Impulses. The ability to control one's impulses matures over the period from 2 to 4. Nonetheless, some children are better able to inhibit their impulses than others. Two concepts have been used to evaluate how well children can manage their impulses: effortful control and delay of gratification. Both of these aspects of impulse control show individual differences as well as maturation over the toddler years.

Three factors account for differences in toddlers' impulse control (see FIGURE 6.3 ▶). First, toddlers differ in their capacity to empathize with the distress of others. Some children appear to be callous, showing little regard for others and little willingness to make reparations when they are the cause of others' distress. Other children are quick to recognize signs of distress in others, offering care and comfort. Individual differences in sensitivity to the distress of others leads to differences in how upset children might be when their behavior causes someone else's suffering, how eager they are to make reparations, and in how willing the child may be to curb that behavior in the future (Colasante, Zuffianò, Bae, & Malti, 2014).

Empathy has both genetic and environmental foundations. In a study of identical and fraternal twins who were 2 years old, the identical twins showed greater similarity in their emotional concern about and response to others' distress than did the fraternal twins. Moreover, harsh or nurturing parenting is related to a child's concern for others. Mothers who showed a stronger concern for others in their childrearing strategies had children whose empathy was more fully developed. Furthermore, girls were observed to be more empathic than boys (Rhee et al., 2013; Waller et al., 2012; Zahn-Waxler, Robinson, & Emde, 1992).

Second, differences in temperament affect self-control. Children who are more aggressive, active, or socially outgoing may experience more situations in which their actions are viewed as disruptive or in need of control. In contrast, children who are more socially inhibited, withdrawn, or passive may encounter fewer expectations to curb or restrict their behavior.

FIGURE 6.3 ▶ Factors Associated with the Ability to Control Impulses

The temperamental characteristic described as **effortful control** refers to a child's ability to regulate his or her response to situations, particularly to inhibit or suppress an automatic response like throwing one's food on the floor and instead to perform a non-automatic response, like saying or gesturing "all done." For example, even when Riley wants to shout out loud, he can talk in a whisper because he sees that Grandpa is napping and he does not want to wake Grandpa. Those infants who are less emotionally intense in their expressions of anger or joy, and who are more cautious in a novel situation, have been found to have greater effortful control in toddlerhood (Kochanska & Knaack, 2003).

Effortful control includes the ability to slow down one's actions on request and suppress movement in response to instructions (e.g., sit still; stop fidgeting; walk, don't run). One measure of effortful control requires a child to move a toy turtle and a toy rabbit along a curved path toward a barn. Effortful control is demonstrated in the child's ability to move the rabbit quickly and the turtle slowly along the same path.

Children show substantial improvement in their effortful control over the period from ages 2 to 4, supported in large part by the continued maturation of executive functions including attention focusing abilities and the capacity for regulating emotional and motor reactions (Li-Grining, 2007; Rothbart & Bates, 2006). However, there are also consistent individual differences that have genetic as well as environmental origins. In a study of identical and fraternal twins, genetic influences accounted for over 60 percent of the variance in the way parents rated their 2-year-olds' ability to inhibit their impulses, with identical twins showing much greater similarity than fraternal twins. However, by age 3, the fraternal twins were becoming much more alike, suggesting that environmental factors were playing a new role. Parents may be expecting their children to function more independently and to show greater patience, and many children are participating in early child care programs where the inhibition of impulses is required in a more structured environment (Gagne & Saudino, 2016).

Third, the capacity for self-regulation may depend on the quality of the parent –infant attachment. Caregiver responsiveness, emotional expressiveness, and a sense of connection are associated with a child's ability to delay gratification. Sensitive caregiving, in which the parent and toddler are able to coordinate their interactions to sustain longer periods of mutually responsive interaction, is associated with an enhanced capacity for self-regulation. Toddlers who experience this rhythmic co-regulation are better able to distract themselves and deliberately guide their attention away from tempting objects that they are not allowed to touch (Kochanska et al., 2010; Li-Grining, 2007).

Since the early 1960s, Walter Mischel and his colleagues have investigated the process by which children delay gratification. To delay gratification, a child must exert willpower in order to resist a strong immediate pull or temptation. This requires shifting attention or distancing oneself from the immediate situation and redirecting attention or action in order to achieve a different goal (Mischel & Ayduk, 2002). For example, when they were at the zoo, Kelly asked for ice cream. Her mother said she could either have ice cream now or go to McDonalds for dinner when they left the zoo. Kelly agreed to wait and go to McDonalds. At age 4, children who delay gratification longer tend to be more intelligent, more likely to resist temptation, demonstrate greater social responsibility, and have higher achievement strivings.

According to Mischel's research, a 4-year-old's ability to use self-regulatory strategies to delay gratification has enduring effects. You have probably watched some version of the famous Mischel marshmallow experiment. Children are asked to wait in a room by themselves where a single marshmallow is sitting in front of them. They are told that when the experimenter returns, they can eat the marshmallow and have another. Children who waited longer in this experimental situation that required a self-imposed **delay of gratification** at age 4 were described more than 10 years later as socially and academically more competent than their peers. Their parents rated these children as more verbally fluent and able to express ideas, using and responding to reason, and more competent and skillful. These children were more attentive and able to concentrate, plan, and think ahead, and they were also seen as better able to cope with frustration and resist temptation (Mischel & Ayduk, 2011; Mischel, Shoda, & Rodriguez, 1989; Morf & Mischel, 2002).

Other longitudinal studies have supported the link between self-control in toddlerhood and subsequent social competence. Children who are able to regulate their emotional reactions and resist temptations in toddlerhood are less likely to violate parental rules, are more likely to plan as they approach new tasks, and as a result, are more likely to be successful in school settings where cooperation and compliance are highly valued (Rothbart, Ahadi, & Evans, 2000; Tangney, Baumeister, & Boone, 2004). Children's self-regulatory competence is associated with many positive outcomes, including better scholastic performance, more successful social functioning, and fewer behavior problems. By adolescence, self-control is a better predictor of academic performance than IQ (Duckworth & Seligman, 2005; Eisenberg, Fabes, Guthrie, & Reiser, 2002). Children who are able to resist temptations are demonstrating that they can outwit their desires, using a variety of strategies to achieve longer-term goals that may be in conflict with immediate pleasure.

As a result of a combination of biological and environmental factors, some children have more difficulty regulating their impulses than others. Children's temperament, the ease with which they become frustrated as well as their inability to focus their attention, interacts with their parents' harsh parenting to compromise the emergence of self-control (Lengua, 2009). Some children show evidence of overcontrol, intense worries and fears, and suppression of emotions. These children who experience unusually intense anxiety are described as having **internalizing problems**. Other children show a lack of ability to suppress their impulses. They experience intense anger in conditions of frustration, an inability to delay gratification, and lack of empathy. Children who experience frequent outbursts of anger are described as having **externalizing problems**. Longitudinal studies link the toddler's inability to manage impulses and later internalizing and externalizing problems (Lengua, Honorado, & Bush, 2007).

The Role of Language and Fantasy in Impulse Control.

Language and fantasy are children's most useful tools for managing impulses. Talking about feelings and needs enables adults to help children understand more about their emotions and to devise strategies for self-regulation. Although we tend to think of self-control as internally initiated and managed, there are many social prompts that foster self-control and help children manage their impulses (Fitzsimons & Finkel, 2010). Thompson (1990) identified four ways that caregivers use talking about emotions to help young children gain impulse control. First, parents articulate the family or cultural rules about emotional expression: "Don't get so excited; calm down!" or "Stop that fussing; big boys don't whine and cry!" These messages give young children an idea about the acceptable levels of impulses or emotional intensity and about the types of emotions that need to be regulated.

Second, adults help modify the intensity of emotions through reassuring or distracting talk. They may try to distract a child who is worried about getting an injection, try to convince the child that the shot won't hurt, or that it will be just a little sting. They may try to comfort a sobbing child by talking about some happy event that will distract the child.

Third, adults give children ideas for ways to manage their impulses. "Why don't you count to 50, and then I'll be ready to go outside with you." They might suggest that the child think of pleasant times from the past or sing a cheerful song. Adults teach children superstitions, rituals, songs, and stories about how people handle their strong feelings. "Whenever I feel afraid, I hold my head erect, and whistle a happy tune, so no one will suspect, I'm afraid" (from *The King and I*).

Fourth, children listen to and imitate adults who talk about their own strong emotions and impulses. Parents have an outlook about whether or not emotions can be expressed, and this outlook permeates the home environment. One father described it this way:

> At least in our household, there is stability. I think with us, there is this stability and this comfort level, so I think some of those emotions that are not necessarily allowed to be showed elsewhere because you don't have security, they can feel comfortable having those emotions because it is a safe place. (Parker et al., 2012, p. 55)

Toddlers who can talk to themselves may be able to control their fears, modify their anger, and soften their disappointments. They may repeat their parents' comforting words, or develop their own verbal strategies for reducing pain and suffering.

The development of symbolic fantasy allows children to create imaginary situations in which disturbing problems can be expressed and resolved. Through fantasy play, toddlers can control situations that are far beyond their real-world capacities (Singer & Singer, 1990; Singer & Singer, 2008). They can punish and forgive, harm and heal, fear and conquer fear—all within the boundaries of their own imagination. Children can use the context of pretense to manage strong feelings and to preserve their emotional control (Galyer & Evans, 2001). When Robbie feels bad about something, he whispers to himself, "Superheroes don't cry." He is making use of fantasy and language to control his emotional state. When children are asked to resist temptation, they use a variety of verbal strategies, including talking quietly to themselves and singing songs to distract themselves (Mischel, Shoda, & Rodriguez, 1989).

Self-Directed Goal Attainment

The second sense in which self-control develops involves toddlers' feelings that they can direct their own behavior and the behavior of others to achieve intended outcomes. During infancy, children become increasingly aware of themselves as causal agents. They make things happen. In toddlerhood, children become much more assertive about their desire to initiate actions, persist in activities, and determine when these activities should stop.

> Benjamin at 27 months, 17 days:
>
> When I put him to bed tonight he bellowed at the top of his lungs for a good five minutes from sheer rage that I wouldn't let him get down on the floor and go on playing with his car. What he wants and doesn't want he can be very noisy about—but he can also obviously be rather confused as to what he does want.… This is especially true in the afternoon after his nap. He may wake up demanding a ride or a walk. By the time he gets downstairs, it has switched to "Want to pway bwocks." (Church, 1966, p. 157)

Toddlers' sense of agency—their view of themselves as the originators of action—expands to include a broad array of behaviors. Children want to participate in decisions about bedtime, the clothes they wear, the kinds of foods they eat, and family activities. They want to do things they see their parents and older siblings doing. They also want to direct the behavior of others—taking you by the hand to show you something, giving you some of their cheesy crackers to taste, or bringing a book and climbing up on the couch for some reading. Their confidence in their own ability to handle difficult tasks is not modified by a realistic assessment of their own skills. According to toddlers, "Anything you can do, I can do better." When they have opportunities to do some of these new and complex things and they succeed, they gain confidence in themselves and their abilities. Toddlers feel themselves to be valuable members of the family as they contribute to routine household tasks, like cooking, washing dishes, or sweeping up crumbs. Their feelings of confidence and value are matched by the acquisition of a wide variety of complex, coordinated skills.

You can see how serious Micah is as she helps her dad prepare a healthy smoothie.

The Role of Language in Self-Directed Goal Attainment. Toddlers use what was described by Piaget (1952) as **egocentric speech** to accompany their behavior. They talk aloud but do not seem to be concerned about whether anyone can hear them or understand them. He described the talk as egocentric because it did not seem to have any social intention. Piaget suggested that the development of communication began with inner thinking of a very private nature.

Vygotsky (1987) proposed a completely different developmental pathway to account for egocentric speech and its function. He represented the scheme as follows:

Social speech → egocentric speech → inner speech

Vygotsky viewed speech as beginning in the social interactions between children and adults or other children. In his view, the first and foremost function of speech is social. Egocentric speech is a transformation of this social speech inward. The child uses speech, initially acquired through interactions with others, to guide behaviors. This speech does not have a social intention; rather, it is a tool for problem solving. Vygotsky viewed egocentric speech and actions as part of the same problem-solving function. The more difficult the problem, the more speech is necessary for the child to find a solution. He noted, "Children solve practical tasks with the help of their speech, as well as their eyes and hands" (Vygotsky, 1978a, p. 26). Eventually, the egocentric speech of an audible nature dwindles (but does not disappear entirely) and becomes inner speech.

The language that guides problem solving emerges from the social interactions with adults and eventually becomes **inner speech**. Often, when young children try to figure out how to work something or how to get something that is out of reach, they turn to adults for help. The talk that adults use as they guide young children is then used by the children themselves to support and guide their own behaviors. Vygotsky referred to this process as the internalization of social speech. In a sense, a child's capacity for self-directed goal attainment depends on what the child has taken in of the spoken, practical advice and guidance given by adults and older peers who have tried to help the child solve problems in the past. In adulthood, these speech-like cognitions are not typically audible; they are experienced as inner talk, or self-talk, that help organize complex tasks (e.g., *first make an outline*), encourage persistence (e.g., *concentrate, stay focused*), or review and revise (e.g., *doesn't fit, try the bigger one*).

Inner speech gives children a new degree of freedom, flexibility, and control in approaching tasks and working toward a goal. They can use words to call to mind tools that are not visible. When striving to solve a difficult problem, young children use private speech both to focus attention on the cognitive aspects of the task, and to manage or regulate their emotions (Damianov, Lucas, & Sullivan, 2012). They can plan steps toward a goal and repeat them to guide their actions. They can use words like *slowly, be careful*, or *hold tight* to control their behavior as they work on a task. Even when engaging in social communication, inner speech may help children regulate their emotions (e.g. *don't yell*; *stay calm*) or clarify their communication (e.g. *find another word*; *talk louder*) (San Martin Martinez, Boada i Calbet, & Feigenbaum, 2011). Language skills and self-control operate together to help children inhibit negative emotions and disruptive behavior during times of frustration (Lynam & Henry, 2001).

In summary, we have reviewed two rather different phenomena under the developmental task of self-control. Children's ability to control their impulses is closely linked to the psychoanalytic concept of delay of gratification, as Freud (1905/1953) used it to describe development during the oral and anal stages. Self-directed goal attainment, sometimes referred to as agency, accounts for children's efforts to increase their competence through persistent investigation and skillful problem solving (Harter, 1982; White, 1960). Self-determination theory assumes that very young children have a natural desire to explore their environment, extend their skills, and achieve new levels of mastery. However, their desire for autonomy and self-directed goal attainment need to be supported and scaffolded by sensitive parenting (Deci & Ryan, 2000). Autonomy-supportive parents foster their toddler's goals, interests, and choices, rather than controlling their behaviors. They may give hints or suggestions as their child tries to accomplish a task, and give encouragement, rather than taking over the task or just telling the child to "work it out on your own" (Whipple, Bernier, & Magneau, 2011).

To function effectively as family members, toddlers must feel confident in their ability to control the inner world of their feelings and impulses and the outer world of decisions and tasks. As toddlers discover that they can tolerate stress, express or withhold their anger as appropriate, and approach difficult tasks and succeed at them, they also lay claim to a growing sense of selfhood.

The more toddlers can do by themselves, the more confidence they have in their ability to control the outcomes of their actions and achieve their goals. Over time, the sense of self-control that is formed during toddlerhood is integrated into adult capacities to overcome obstacles to achieve important goals and to engage in acts of generosity and kindness even when these acts conflict with their own immediate needs.

FURTHER REFLECTION *Why is self-control emphasized as a primary developmental task in toddlerhood? How does it relate to the theme of autonomy versus shame and doubt?*

Do you know people who have limited self-control? Others who appear to be "over-controlled"? Speculate about how individual differences in self-control play out in later stages of childhood, adolescence, and adulthood.

The Psychosocial Crisis: Autonomy Versus Shame and Doubt

OBJECTIVE 5 Define the psychosocial crisis of autonomy versus shame and doubt, the central process of imitation, the prime adaptive ego strength of will, and the core pathology of compulsion.

During toddlerhood, children become aware of their separateness. Through a variety of experiences, they discover that their parents do not always know what they want and do not always understand their feelings. In early toddlerhood, children use rather primitive devices to explore their independence. They may say "no" to everything offered to them, whether they want it or not. This is the period that people often refer to as the terrible twos. Toddlers seem very demanding and insist on having things done their own way.

Autonomy

The positive pole of the psychosocial crisis of toddlerhood is autonomy. During this period of life, autonomy refers to the ability to behave independently—to perform actions on one's own. Children do not just prefer to do most things on their own, they *insist* on it. Once children begin to work on a task, such as putting on pajamas or tying shoelaces, they will struggle along, time after time, until they have mastered it. They may adamantly reject help and insist they can manage on their own. They will allow someone else to help them only when they are sure that they can progress no further by themselves.

In most cultures, expectations for autonomy are expressed as encouragement for children to perform daily tasks, such as dressing and feeding themselves, playing alone or with peers, and sleeping apart from parents. The exact list of expectations and the age at which these behaviors are to be accomplished varies from one society to the next. Within U.S. society, pressures for autonomy are often expressed in early expectations for skill acquisition and verbal expressiveness. Families in the United States are especially enthusiastic about fostering autonomy, starting with early weaning and separate sleeping arrangements for infants and continuing with efforts to support early locomotion with walkers, scooters, and other toys that foster toddlers' independent movement.

In many non-Western cultures, *interdependence* rather than independence is the valued goal of socialization. Children are likely to experience pressures toward autonomy with the birth of a sibling. Rather than pressing for separateness and distance from the caregiver, toddlers may hover near their mother, distressed at her new lack of availability. Through guidance from older siblings and peers, young children learn to participate in the ongoing activities of the household, watching intently, imitating others, and contributing as they can to daily tasks. Within this cultural context, expectations for autonomy may emphasize the ability to demand less of the mother, to become sensitive to the needs of others, and to function cooperatively with peers (Edwards & Liu, 2012; Harkness & Super, 2012).

At 2 ½, Sadie is already getting ready to engage in some autonomous scooting, not too fast, but on her own.

The establishment of a sense of autonomy requires not only tremendous effort by the child, but also extreme patience and support from parents. Toddlers' demands for autonomy are often exasperating. They challenge their parents' good sense, goodwill, and good intentions. Parents must learn to teach, cajole, absorb insults, wait, and praise. Sometimes, they must allow their children to try things that the children may not be able to do. By encouraging their children to engage in new tasks, parents hope to promote their sense of competence.

Autonomy-supportive parenting has been defined as incorporating the following characteristics (Joussemet, Landry & Koestner, 2008):

1. Providing rationale and explanation for behavioral requests
2. Recognizing the feelings and perspective of the child
3. Offering choices and encouraging initiative
4. Minimizing the use of controlling techniques

Autonomy-supportive parenting is distinguished from controlling parenting, in which parents use more commands and insist on immediate compliance (Harvey et al., 2016), and from permissive parenting in that it includes active engagement with the child and clear expectations for behavior (Joussemet, Landry, & Koestner, 2008). An underlying motivation is to foster the child's emerging self-regulation and internal motivation, not simply to insist on compliance. Autonomy-supportive parenting has been found to be predictive of higher levels of self-regulation and social competence in toddlerhood as well as subsequent school achievement and socioemotional development in later childhood and early adolescence (Bindman, Pomerantz, & Roisman 2015; Matte-Gagné, Harvey, Stack, & Serbin, 2015).

In the development of autonomy, toddlers may go through a period of somewhat rigid, ritualized, unreasonable nay-saying, but eventually they establish a more enthusiastic, energetic desire for independent action (Erikson, 1963). The behavior of older toddlers is characterized by the phrase "I can do it myself." Toddlers demonstrate an increasing variety of skills. Each new accomplishment gives them great pride. When doing things independently leads to positive results, the sense of autonomy grows. Toddlers begin to create an image of themselves as people who can manage situations competently and who can satisfy many of their own needs. Children who have been allowed to experience autonomy should, by the end of toddlerhood, have a strong foundation of self-confidence and feelings of delight in behaving independently.

Shame and Doubt

Some children fail to emerge from toddlerhood with a sense of autonomy. Because of their failure at most attempted tasks, because of continual discouragement and criticism from caregivers, or most likely because of both, some children develop an overwhelming sense of shame and self-doubt. This is the negative resolution of the psychosocial crisis of toddlerhood (Erikson, 1963). **Shame** is an intense negative emotion that focuses on a negative evaluation of the self. Often it is accompanied by a sense of having been exposed or ridiculed and made to feel inferior to others. When young children were observed in a shame-inducing situation, they exhibited physical tension, avoided eye contact, and were reluctant to talk (Bafunno & Camodeca, 2013). Feelings of shame do not have to occur in the presence of an audience; however, they usually involve at least an imagined notion of how one's behavior might look to others (Tangney, 2001). The literature often discusses shame and guilt as two negative "moral" emotions. But they are really distinct emotions with different precursors and quite distinct relationships to moral development. We will consider the nature of guilt as a feature of the psychosocial crisis of early school age in chapter 7.

One source of shame is social ridicule or criticism. You can probably recall feelings of shame for having had some kind of accident—you spilled your milk or wet the bed or got dirt on your new outfit. Early experiences of shaming are often linked to toilet training (see the **Human Development and Diversity** box Toilet Training). Shame generally originates in an interpersonal interaction in which a child is made to feel embarrassed or ridiculed for behaving in a stupid, thoughtless, or clumsy way (Tangney, Wagner, Fletcher, & Gramzow, 1992). The child may have acted without considering the consequences or was unable to control his or her actions. When you are shamed, you feel small, humiliated, and helpless. Some cultures rely heavily on shame coupled with opportunities for restitution as a means of social control. Children in these cultures grow up with a strong concern about how their behaviors might reflect on their family or result in disrupting the social bond with their community. One of their greatest fears is to be publicly accused of immoral or dishonorable actions that would bring disgrace to their family (Scamier, Schmader, & Lickel, 2009; Scheff, 2003).

The quality of early attachment relationships can also contribute to experiences of shame. Attachment theory suggests that in the process of ongoing interactions between infants and their caregivers, children form an internal working model of self and other. If the child's working model of the parent is rejecting, indifferent, or unpredictable, this is likely to be linked to a sense of the self as unworthy or unlovable. In toddlerhood, the child's representations of self and other become more readily observable in the way they talk about themselves and in their fantasy play. Children whose earlier attachments were insecure are more likely to form a negative representation of the self, including expressing anger, blame, or shame about their actions or feelings (Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009).

As children construct an idea of what it means to be a good, decent, capable person, they build a mental image of an ideal person. Children feel shame when their behavior does not meet the standards of their ideal, even though they have not broken a rule or done anything naughty. In general, shame is associated with feelings that the whole self is bad or worthless. It makes one want to disappear from the eyes of others. Children who have frequently been shamed by their parents in toddlerhood are also likely to exhibit early signs of depression. These two emotions, depression reflecting feelings of worthlessness and helplessness and shame reflecting experiences of parental disappointment or humiliation, are likely to go hand in hand (Luby et al., 2009).

Shame is extremely unpleasant. In order to avoid it, children may refrain from all kinds of new activities. Children who feel shame lack confidence in their abilities and expect to fail at what they do. The acquisition of new skills becomes slow and painful when feelings of self-confidence and worth are replaced by constant doubt. Children who have a pervasive sense of **doubt** feel comfortable only in highly structured and familiar situations in which the risk of failure is minimal. Intense feelings of shame and doubt do not generally result in restitution or prosocial behavior. Rather, shame and doubt often motivate denial, defensiveness, anger, and aggression (Tangney & Dearing, 2002; Tangney & Mashek, 2004). Children's proneness to shame and guilt has been found to predict risky and illegal behaviors in young adulthood (Stuewig et al., 2015).

All children experience some failures amid their many successes. In the process of achieving a new level of separateness, children may discover that they have harmed a loved one, broken a treasured toy, or wandered too far away and become separated from the caregiver at a crowded store or an unfamiliar park. Toddlers often exhibit periods of ambivalent dependency alternating with unrealistic self-assurance as they try to establish a comfortable level of independence from the loved one. The successful outcome to this process requires flexibility and warmth on the part of caregivers who accept and welcome the emerging selfhood of their child while building support for appropriate levels of self-control.

The Central Process: Imitation

Imitation is one of the most widely used and efficient mechanisms for learning. Along with teaching and practice, imitation is a basic mechanisms that supports cultural transmission over generations. Children observe their more skillful parents, siblings, and peers. Each successive generation benefits from observing the skilled behaviors of the previous generation (Caldwell & Millen, 2009). Imitation plays a role in skill learning as well as in social cognition, allowing one person to observe and reproduce the actions, expressions, and gestures of others. Although imitation requires the presence of active models, its outcome is a shift of the action from the model to the imitator. Once toddlers succeed in imitating a certain skill, that skill belongs to them, and they can use it for any purpose they like.

Toddlers seem driven to imitate almost everything they observe. Toddlers' vocabularies expand markedly through their imitation of the words they hear in adult conversations, on television, and in stories. Their interest in dancing, music, and other activities stems from imitation of parents and peers. When one

Toilet Training

Every human culture has practices to remove waste products from close proximity to the social group. The effort to teach children how to dispose of human waste in a culturally appropriate fashion is the focus of what we in the United States refer to as *toilet training* or *potty training*. Any approach to this task reflects a combination of technology, beliefs, and practices. One of the basic issues is whether one believes that the regulation of this training should be left to the child, drawing on a sense of developmental readiness, or given over to others, which usually suggests a training program (Valsiner, 2000).

In psychoanalytic theory, toilet training symbolizes the classic psychological conflict between individual autonomy and social demands for conformity. Children must subordinate their autonomy to expectations for a specific routine regarding elimination. In the United States, the contemporary approach to this dichotomy between autonomy and conformity is advocated by the American Academy of Pediatrics (American Academy of Pediatrics, 2016; Stadtler, Gorski, & Brazelton, 1999). The American Academy of Pediatrics website has an extensive list of articles addressing various aspects of toilet training, including readiness, choosing a potty, and dealing with accidents (https://www.healthychildren.org/English/ages-stages/toddler/toilet-training/pages/default.aspx).

Their advice about toilet training combines waiting until the child is ready and introducing toileting in a guided, systematic fashion. They suggest three areas of readiness: physical maturation, including the ability to sit, walk, dress, and undress; cognitive maturation, including the ability to understand and comply with directions; and social maturation, including the desire to imitate and identify with adults as well as a desire for self-determination and mastery. The process is expected to begin at around 18 months when infants show some interest in the potty and be complete by around age 4 when toddlers will be able to accomplish both day time and night time toileting. Even when they are managing well during the day, many children continue to have difficulty staying dry through the night well into their middle childhood years.

Margaret Miller/Science Source

Spencer is able to relax on a potty just his size, taking advantage of a few quiet moments for reading as he develops his toilet habits.

Experts suggest starting with bowel training and then moving on to urinating in the potty by allowing the child to play near the potty, dropping the contents of the dirty diaper in the potty so the child sees the connection, reminding the child to use the potty when needed, but not to show disappointment when he or she misses or forgets. Patience, reassurance, and praise are suggested while the caregiver encourages increasing compliance with toileting practices (Mayo Clinic, 2014).

This approach, which you may find extremely sensible and right, can be contrasted with the practices of the Digo, a group living in coastal Kenya and Tanzania. The Digo live in huts with mud floors. The smell of urine mixed with the mud is extremely unpleasant and difficult to remove. So the Digo are eager to have their infants urinate out of the hut as early as possible. Training begins at 2 to 3 weeks of age. The caregiver sits on the ground outside the hut with feet outstretched and places the baby in the appropriate position for urinating. The baby is placed on the caregiver's feet, facing away from the caregiver but supported by the caregiver. While in this position, the caregiver makes a low sound ("shuus"), which serves as a conditioned stimulus for urination. This is repeated frequently, day and night, until the baby urinates in this position following the sound. When this happens, the baby is rewarded with breastfeeding. By the age of 4 to 5 months, Digo babies are trained to urinate only in the culturally approved position and setting (De Vries & De Vries, 1977). In contrast to the recommendations of the American Academy of Pediatrics, this approach places a strong emphasis on training and shows a perception of readiness that is much earlier than the perception of readiness held in the United States and other Western cultures.

Critical Thinking Questions

1. Apply what you have read about toddlerhood, including physical, cognitive, language, and emotional development, to the process of toilet training. What are some developmentally appropriate practices that could support this important goal?
2. Explain how toilet training is related to the themes of autonomy versus shame and doubt.
3. Discuss the role of self-control, including self-regulation and self-directed goal attainment, in toilet training.
4. Compare and contrast the cultural beliefs and goals implied by the U.S. and the Digo approaches to toilet training.
5. Discuss possible caregiver reactions to toileting. Include ways they may foster autonomy or create feelings of shame and doubt.

Every morning Micah sees her dad read the paper. Now she likes to do this herself even though she can't read yet.

child in a play group makes a funny noise or performs a daring act, other children seem compelled to recreate this novel behavior.

The imitative behavior of toddlers is different from the socially induced conformity observed in older children. Toddlers are not aware of a great many social norms and therefore feel little pressure to conform to them. Their imitative behavior is really a vehicle for learning. Every act becomes their own, even if it has been inspired by others. There are two complementary motives for imitation during toddlerhood: One is the drive for mastery and skill learning; the other is the drive to feel connected to the social group (Over & Carpenter, 2013).

> Jess liked to imitate adult tasks. When his mother cleaned the house, he followed her with a cloth, trying to dust the tables. When Mark (*Jess's older brother*) fed the dog, Jess helped him by getting the dog's dish. When his father shaved in the morning, Jess took a toothbrush to imitate his father with lathering and shaving motions. He was learning to brush his teeth, even though his span of attention was short at this job and the cleansing ineffective. (Brazelton, 1974, pp. 139–140)

Imitation is a means of participating in and sustaining social interactions, and advancing social cognition (Meltzoff, 2010). In a peer setting, imitation emerges as a strategy for children to coordinate their behaviors with those of other toddlers. Before verbal communication becomes a truly useful tool for establishing or maintaining social contact, toddlers use imitation to feel connected to one another and begin to invent coordinated games. Imitation advances empathy. By watching and repeating the actions of others, toddlers begin to gain insight into the other person's experiences and emotional state (Rogers & Williams, 2006). Imitation can also be a way to reestablish a sense of belonging after experiences of exclusion or rejection. By mimicking others, especially those the child wants to be connected to, the child increases the target's feelings of liking, closeness, and trust (Lakin, Chartrand, & Arkin, 2008; Watson-Jones, Whitehouse, & Legare, 2016).

The emphasis on imitation highlights the central role of culture at this period of life. In many cultures, adults orient young children toward important tasks and expect them to watch and learn in a process of imitation and shared problem solving (Rogoff, Mistry, Goncu, & Mosier, 1993). Daily events provide models for imitation and reflect the culture of families and communities. Toddlers rapidly accumulate the vocabulary of speech and action that belongs to their cultural group. How visitors are greeted when they arrive at the home; how adults groom themselves, dress, and speak to one another; how household tasks and chores are performed; how older children amuse themselves; how young people and older people treat each other—the thousands of words, gestures, and rituals of daily life make up the culture absorbed by watchful toddlers as they arm themselves with the resources to press toward autonomy.

Given its pervasive role in the early development of children, it is not surprising to learn that imitation is supported by specific neural mechanisms. Research has identified a **mirror neuron system** that underlies a person's ability to observe and then recreate the actions of others as well as to understand the emotions and intentions of others (Iacoboni & Dapretto, 2006; Iacoboni, 2009). The mirror neuron system in humans is a coordinated network of three areas: One area gathers visual information; one recognizes and processes the motor components of the visual information; and one processes the goal of the action. Information from the goal-oriented area is sent back through the system to match up with the original visual information to guide motor behavior. The system supports sensory and motor integration while the person is observing others, imitating others, and being imitated by others. These neurons show activity during observation, and even greater activity while one performs an action that was observed when watching others—in other words, when one is imitating something one is watching. The mirror neurons are sensitive to the intention of the action as well as to the actions themselves. For example, a different pattern of neural firing in the mirror neuron system is observed when a grasping action is linked to drinking from a cup and when grasping is linked to taking the cup away from the table to clean up. The mirror neuron system is considered to be a key to clarifying empathy and our ability to understand others through imitation of facial expressions, body posture, and gestures. Disruptions of the mirror neuron system may be implicated in the social deficits associated with autism (Gallese, 2006).

The Prime Adaptive Ego Quality and the Core Pathology

As a result of the resolution of the psychosocial crisis of autonomy versus shame and doubt, toddlers emerge with the prime adaptive ego quality of will or the core pathology of compulsion.

The ego quality of will provides a sense of being in control of one's thoughts and actions. It is vital to emerging capacities for self-expression, self-direction, and eventually self-fulfillment. In contrast, the core pathology of compulsion reflects pervasive anxiety. Thoughts impose themselves; actions must be carried out over and over. The will is taken hostage by unbidden impulses that must be satisfied.

Will

Erikson et al. (1986) identified the prime adaptive ego quality that emerges through the successful resolution of the psychosocial crisis of toddlerhood as **will**—the capacity of the mind to direct and control action. It is closely linked to the idea of self-directed goal attainment. Will is the inner voice, focusing attention, encouraging, and urging one on, especially in the face of obstacles. It provides the psychological energy that allows people to press harder in competition, work to surpass previous achievements, and reach for new goals. In the face of disability, it is the force that urges the person to make peace with the loss and focus on alternate goals. In the face of crisis, people often refer to their will to survive as the fundamental strength that kept them looking for new solutions or that prevented them from giving up hope. In older people who experience potentially spirit-crushing, painful losses or disabilities, will is the force that provides buoyancy as they learn to accept their decline, and look for areas of continued mastery.

Sometimes, we think of will in a negative way, as associated with stubbornness or overbearing dominance, that is, bending to someone's will. But the meaning of will in the psychosocial context refers to the sense of inner determination and purpose that permits a person to set goals freely and make persistent efforts to achieve them. It reflects the positive connotation of the term *willpower,* the ability to sustain effort and delay gratification in order to achieve a long-term goal (Mischel & Ayduk, 2011). Will leads to a positive belief in oneself as someone who can make things happen. When you see a child struggling to carry a heavy box or drag a wagon filled with toys up a steep hill, you see will in action. When you watch an older child chew and twist a pencil trying to figure out a tough math problem, you see will in action. And when you go to the high school swimming pool at 6:00 in the morning and see students working out or swimming laps to get ready for an upcoming meet, you see will in action.

Courtesy of Philip and Barbara Newman

Will reflects an inner determination to persist toward a goal. Micah shows her will as she pedals fast to reach the neighbor's house, leaving Papa and Grandma far behind.

Compulsion

Will provides a voluntary energy and focus to action. In contrast, **compulsions** are repetitive behaviors that are motivated by impulse or by restrictions on the expression of it. They are nonspontaneous and unchanging. Compulsions are a close relative to the *ritualization* that is developed in toddlerhood. Children at this stage typically devise some well-ordered rituals, especially around important transitions such as going to bed, getting dressed, and leaving the house. They insist that these rituals be followed precisely and become distressed if the rituals are violated. Rituals are efforts to bring control and order to the environment. They are often associated with fears, such as fear of strangers or separation from loved ones for younger children, or fears of environmental threats such as burglars or illness in somewhat older children (Evans, Gray, & Leckman, 1999). Rituals help provide feelings of sameness and continuity during changes in setting or state that may threaten toddler's feelings of selfhood.

> Benjamin at 27 months, 17 days:
>
> His bedtime rituals are changing but still evident. He must be read to—as many books as the reader will stand for—and his music-box must be wound up. And I don't think he knows it's even possible to sleep any way except on the stomach. But he doesn't ask for his three old favorite stories to be told to him any more (thank heaven) and he doesn't always ask to be sung to—sometimes he wants one of three or four particular songs, but by no means always. (Church, 1966, p. 159)

Toddlers' rituals usually do not repeat adult ways of doing things; they are not mere imitations of adult rituals. Their rituals, however, like those of adults, serve the important psychological function of bringing order and a sense of mastery to the unknown or the unpredictable. In comparison to adaptive rituals that actually provide a sense of comfort and relief from uncertainty, compulsions must be carried out again and again, never adequately resolving the anxiety that motivates them.

Obsessive-compulsive disorder (OCD) is a clinical diagnosis of an anxiety disorder that has been increasingly observed among children and adolescents. **Obsessions** are persistent, repetitive *thoughts* that serve as mechanisms to focus anxiety. An obsession is a disturbing idea that cannot be set aside, even if the person realizes that the idea is unreasonable or unlikely. Compulsions are repetitive, ritualized *actions.* A person may try to get rid of a worrisome obsession by carrying out a ritualized set of behaviors. However, the thoughts that trigger anxiety are not permanently resolved through the actions, so the cycle of thoughts and actions have to be repeated again and again. For instance, a person with an obsessive-compulsive disorder may become committed to repeated handwashing to rid the self of preoccupying thoughts about uncleanness. The compulsive handwasher "scrubs his hands in tortured solitude, until they become raw, and yet he never feels clean" (Erikson, 1977, p. 78). Over time, a neurosis may become disruptive to daily life because it takes a lot of time, makes it hard to concentrate on tasks, and the person feels a loss of control.

Cases of OCD have been documented as young as 4 years of age. The pattern of symptoms observed in children and adolescents tends to differ from the pattern observed in adults, and among children the number and severity of symptoms can be quite diverse. Common groups of OCD symptoms among children include (1) mental rituals, touching, and ordering, (2) contamination and cleaning, (3) superstitions, (4) obsessions/checking and confessing, and (5) somatic concerns (Ivarsson & Valderhaug, 2006). One case study described a child who had obsessive fears of choking on a big object at age 4 and needed repeated reassurances that this would not happen. By age 9, the child was diagnosed with OCD (Geffken, Sajid, & MacNaughton, 2005). An overview about the nature of OCD can be found in the brochure published by the National Institute of Mental Health: *Obsessive-Compulsive Disorder: When Unwanted Thoughts Take Over* (NIMH, 2010).

In a sense, people who suffer from obsessions and compulsions have a damaged will. Their ability to willfully direct their thoughts and actions toward a goal is impaired. Rather, they feel that their thoughts and actions are being controlled by some powerful force outside their voluntary control. It is not the same as a hallucination. People with compulsions or obsessions do not think that someone from outer space or some voice from the spirit world is telling them what to do. They recognize the directive as coming from their mind, but not from their will.

Compulsions represent the ego's attempts to provide some structure to reality, but they do not work to promote further development because they are not meaningful (Erikson, 1982). The experience of the doubt-filled, shame-ridden person tends to be continuously unpleasant, uncertain, and sometimes tortuous. Life is enacted around carefully orchestrated patterns of meaningless, compulsive behaviors. The **Human Development and Diversity** box explores autism spectrum disorders, a complex array of developmental disabilities that typically include symptoms involving intense, repetitive behaviors and difficulties with social communication.

FURTHER REFLECTION *How does culture influence the expression of the psychosocial crisis of autonomy versus shame and doubt?*

What are the societal forces that foster the sense of autonomy in toddlerhood? What are the forces that create a sense of shame and doubt?

What are some adaptive functions of rituals? How can you determine if a toddler's rituals are a symptom of a more serious mental disorder?

The Impact of Poverty on Psychosocial Development in Toddlerhood

OBJECTIVE 6 Evaluate the impact of poverty on development in toddlerhood.

In 2014, approximately 47 percent of U.S. children under the age of 6 lived in low-income families (family income is up to 200 percent above the poverty threshold) and 24 percent (5.5 million children) lived in poor families (the family income is at the poverty threshold or below). In 2014, the federal poverty level for a family of three with one child was $19,055 or less. In fact, this is much less than it costs to meet basic needs for housing, food, transportation, health care, and child care expenses. The National Center for Children in Poverty estimates that a family of three would need roughly twice this amount to meet basic needs, an amount that varies by regions of the country as well as urban, suburban, and rural communities (Jiang, Ekono, & Skinner, 2016). In a comparison of 20 rich countries around the world, the United States has the dubious distinction of having the highest percentage of children (21.1 percent) living in poverty (Gornick & Jäntti, 2016).

Poverty and Brain Development

Poverty is associated with conditions that are disruptive to optimal development, including food insecurity, poor nutrition, inadequate health care, poor mental health, limited parental education, child abuse and neglect, lack of stimulating parent–child interactions, and harsh punishment (Yoshikawa, Aber, & Beardslee, 2012). In the first years of life, rapid growth and interdependence among cognitive, social, and physical domains mean that significant modifications in any one system can have a substantial impact on the others. Early malnutrition, iron deficiency, exposure to environmental toxins such as lead, lack of adequate stimulation, and exposure to harsh or neglectful parenting can all impact brain development, including reactivity to stress, ability to regulate anxiety, executive control, memory, and attention (Rodier, 2004; Semeniuk, 2013). It is not surprising that living in poverty, especially conditions that create heightened stress for parents, is associated with high rates of cognitive challenges for children, particularly difficulties with inhibitory control and attention regulation (Lempinen, 2012).

Poverty and Health

Many children from low-income families have no regular source of health care and have not been immunized for measles and

HUMAN DEVELOPMENT AND DIVERSITY

Autism Spectrum Disorder

What Is Autism Spectrum Disorder (ASD)?

ASD is a general term that refers to a range of complex neurodevelopmental disorders characterized by (1) social impairment, (2) communication difficulties, and (3) restricted, repetitive, stereotyped patterns of behavior. According to the CDC, 1 child out of every 68 has some form of ASD.

What Are the Symptoms or Signs of ASD?

The symptoms associated with ASD are typically observed by the age of 2. They may range from mild to severe. In some cases, children may develop normally in infancy, and then show symptoms in toddlerhood. They stop using language, playing, or enjoying interacting with others.

Symptoms observed in infancy, often by 18 months:

Unresponsive to others
Focuses on one item intently to the exclusion of all else
Does not respond when called by name
Avoids eye contact

Symptoms observed in toddlerhood:

Delayed use of language
Lack of empathy
Difficulty interpreting or responding to what others are feeling
Difficulty understanding social cues
Special attachment to one particular object
Likes to line things up; have objects in a specific order
Repetitive movements; self-harming behaviors
Refers to self by name, instead of me or I

Autism intensifies the nature of tantrums

Tantrums do not subside readily
The child may appear not to be able to control behaviors
The child does not respond to parental soothing, talk, or threats
Intense responses: Screaming, crying, resisting contact, pushing others away

Sensory sensitivities

Unusual sensitivity to light, touch, smell, sounds, or taste
Over- or under-reaction to pain or loud noises
Distinctive food preferences

What Causes ASD?

As the term implies, ASD is a complex condition with a variety of symptoms of varying intensity. The condition is considered to be primarily caused by genetic factors, but the root causes are not fully known.

- Twin studies show that if one twin has ASD, there is a 90 percent chance that the other identical twin will also be affected. This supports a genetic basis for ASD.
- Irregularities in brain development, including abnormal levels of serotonin and other neurotransmitters, suggest genetically-based problems in how brain cells communicate with each other.
- These genetic predispositions may be activated by certain environmental conditions in the prenatal period, especially the presence of a virus, or paternal age.

Even if the condition has a genetic basis, it is unlikely that most cases of autism can be traced to one gene. Researchers are identifying a large number of genes that are associated with ASD. What is more, autism has been linked to new mutations in the sperm or egg cells that form the offspring, suggesting some problem in DNA replication, not a condition that is inherited from the parents (Makin, 2015).

What Treatments Are Effective for ASD?

There is no cure and no single best treatment. This is a lifelong condition. However, early screening and early intervention have the best chance for reducing the severity of symptoms and supporting normal development. Common treatment methods include:

- Behavioral management to reinforce desired behaviors and to minimize undesired behaviors.
- Speech and language therapy, occupational therapy, physical therapy.
- Special services within schools: one-to-one or small group instruction, design of an IEP and ongoing evaluation of progress.
- Medications to reduce anxiety and control hyperactivity

Controversies Around ASD

Although ASD is considered a developmental disability, people with ASD are also known to have many strengths including (NIMH, 2016):

- Having above-average intelligence: the CDC reports 46 percent of ASD children have above average intelligence
- Being able to learn things in detail and remember information for long periods of time
- Being strong visual and auditory learners
- Exceling in math, science, music, or art

Thus, some prefer to use the term "neurodiversity" rather than disorder or disability, suggesting that ASD is one expression of a wide range of neurobiological differences in human cognitive functioning that can be adaptive in some contexts and disruptive in others.

There is a burgeoning literature on ASD. You can find more information at the Center for Disease Control and Prevention website, http://www.cdc.gov/ncbddd/autism, and the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) website, http://www.nichd.nih.gov/health/topics/autism/Pages/default.aspx.

Critical Thinking Questions

1. What are the signs and symptoms of autism spectrum disorder that you might look for in infants and toddlers?
2. What community resources are available if you suspect that a child has an autism- related condition?
3. What are the pros and cons of thinking of ASD as neurobiological diversity as contrasted with a developmental disability?
4. There is a great deal of ongoing research into the causes and possible treatments of ASD. Using your Internet search skills, what can you find out about new discoveries in this field?

Sean Sprague/Alamy Stock Photo

These Cambodian boys help their mother scavenge for resources in the garbage dump near their village. You can imagine all the health risks associated with this activity and their impact on the boys' development.

other infectious diseases. Repeated bouts of illness combined with poor nutrition detract from a child's energy. The combination of malnutrition and illness has multiple consequences, including the possibility of structural brain damage, lethargy, delayed physical growth, and, as a result, minimal exploration of the environment. All these factors taken together produce what has been observed as delayed psychomotor and cognitive development in toddlerhood (Brown & Pollitt, 1996; Pollitt, 1994). Poor health in childhood has a lasting impact on adult health (Halfon, Inkelas, & Hochstein, 2000).

Poverty Impacts the Parenting Environment

Families in poverty are a diverse group, characterized by a range of conditions that could present challenges to optimal development. Think about Harrison who came from a chaotic home environment, but whose mother placed him in a caring preschool. With the support of thoughtful early childhood teachers, Harrison was able to manage his outbursts, become more relaxed, and enjoy being part of the preschool group. Love, caring, warmth, and responsiveness can produce children who emerge from impoverished conditions with great strengths.

The specific consequences of poverty depend on the ways in which poverty impacts the childrearing environment. For example, young mothers whose education is disrupted by early childbearing and mothers who are suffering from depression are also likely to have reduced financial resources. However, educational level and depression are associated with different consequences for children. Mothers' educational attainment is strongly associated with their children's vocabulary and school achievement. Among low-income families, children whose mothers have had fewer years of school have lower levels of school readiness and do worse on standard measures of academic achievement. Maternal depression is a different risk factor, associated with the child's social skills. Children whose mothers are depressed are less cooperative, less compliant, and show more evidence of oppositional or defiant behaviors in preschool (Perry & Fantuzzo, 2010).

Poverty and Academic Outcomes

Early exposure to poverty can have lasting consequences for adult outcomes, especially outcomes related to academic achievement and cognitive abilities. A combination of factors tied to family poverty, including exposure to harsh parenting, disruptions in emotional regulation, and the absence of positive interactions with adults, results in a lack of school readiness and a trajectory of lower academic motivation and subsequent disengagement from school. The benefits of attending high quality preschool for children in low-income families are well known. Preschool enrollment contributes to school readiness, positive attitudes toward schooling, and a reduced risk of dropping out of school. Yet, for a variety of reasons, many parents do not enroll their young children in Head Start or other high quality programs: difficulty in finding *high-quality, affordable* programs in low-income neighborhoods; the number of young children in the family; parental education; and constraints associated with a mother's work schedule (Crosnoe, Purtell, Davis-Kean, Ansari, & Benner, 2016; Pew Research Center, 2015b).

The link between childhood poverty and life-long educational and career attainment is well-documented. A clear connection was found between exposure to poverty in the first 5 years of life and reduced income and hours of work after age 25 (Duncan, Ziol-Guest, & Kalil, 2010). One model for explaining this process focuses on the likelihood that extreme poverty brings with it exposure to **toxic stress**, intense and frequent traumatic events that persistently activate the stress response. Toxic stress in childhood is associated with disruptions in the neurobiological systems that contribute to learning, memory, and cognitive and emotional control. These problems are linked to difficulties in academic performance, heightened risks of mental health disorders associated with anxiety and depression, and maladaptive coping strategies that impact health such as substance abuse and overeating in the absence of energy needs (Hill et al. 2016). You can appreciate how childhood exposure to toxic stress might result in reduced educational attainment, mental health and physical health problems, and impaired cognitive functioning, limiting occupational opportunities and forcing the young person to remain in the impoverished community where continued exposure to toxic stress is likely (Shern, Blanch, & Steverman, 2016).

Poverty Worldwide

In a worldwide analysis Sally Grantham-McGregor and her colleagues estimated that over 200 million children under the age of 5 are exposed to such extreme conditions of poverty, malnutrition, and neglectful care that they are at critical risk for disrupted developmental outcomes (Grantham-McGregor et al., 2007). Poverty for these children is associated with inadequate food supplies, poor sanitation, increased infections and illness, and growth retardation. The mothers of these children have had limited education, and the home environment is barren and unstimulating.

In many countries around the world, poor families live in high-risk neighborhoods where children are likely to be exposed to toxic stress and chaotic conditions, including disruptions in basic services such as water or electricity, violence, and family instability (Ceballo & McLoyd, 2002; Evans et al., 2005). Even in the United States, parents whose incomes are $30,000 or below are more likely to describe their neighborhoods as dangerous places. They are more likely to worry that their children will get beat up, attacked, or shot, or that they might get in trouble with the law (Pew Research Center, 2015a). In many poor communities, schools are inadequate, adults have completed fewer years of schooling, and there is relatively little encouragement for education. As a result, the children who live in extreme poverty will attend fewer years of school and have less earning potential as adults. As they enter adulthood, they will have more children than adults who had more years of education and be less able to provide the educational or economic resources for their children that will support optimal growth in the next generation. Investment in the nurturance, safety, education, health, and nutrition of young children worldwide is critical in order to alter the trajectory of an intergenerational pattern of lost developmental potential.

FURTHER REFLECTION *What are some implications of Grantham-McGregor's assessment that 200 million children worldwide are exposed to conditions of extreme poverty? Given what you know about development in infancy and toddlerhood, how might early and ongoing exposure to poverty impact a country's economic, social, and political future?*

What do you think might be the most effective two or three policies that could buffer children from the negative long-term impact of poverty on development?

Applied Topic: Child Care

OBJECTIVE 7 Apply a psychosocial analysis to the topic of child care, emphasizing the impact of the kind of care and the quality of care on development during toddlerhood.

Every person who expects to combine parenting and employment or schooling must give some thought to how to provide **child care**. In the United States, child care arrangements are highly diverse. Child care in the United States is covered by minimal federal and state regulations. Thus, children are in the care of a wide range of caregivers with varying types of education and training, from no specific background and training at all to bachelor's and master's degrees.

Because of the growing national need for child care and the wide choice of child care arrangements, parents, educators, and policymakers are asking such critical questions as: What is the optimal child care arrangement for specific children, especially for infants versus toddlers and for children with particular disabilities or temperaments? How does child care influence the development of young children? What is our obligation to ensure quality child care for the children of working parents? What is our obligation as a society to meet the health, nutrition, and safety needs of the children of poor parents?

In 2011, 61 percent of children under the age of 5 were in some type of child care arrangement. This means that a parent or guardian identified one or more types of arrangements that were used at least once a week. The remaining 39 percent of children had no regular arrangement, meaning that they might be in school, in self-care, or in arrangements that varied from week to week (Laughlin, 2013).

In the national survey of child care arrangements, child care providers were classified as relatives or nonrelatives of children. *Relatives* included mothers, fathers, siblings, and grandparents; *other relatives* were aunts, uncles, and cousins. *Nonrelatives* included in-home babysitters, neighbors, friends, and other nonrelatives providing care in either the child's or the provider's home. Another subcategory of nonrelative care was *family day care providers* who care for two or more children outside of the child's home. *Organized child care facilities* included day care or child care centers, nursery schools, preschools, and Head Start programs. Kindergarten/grade school was also included in the organized care total for children 0 to 4 years of age. The largest group, 42 percent, was in care with a relative; 23.5 percent in some type of organized center-based care; and 11 percent in some form of nonrelative care. Eighteen percent were in multiple arrangements on a regular weekly basis (Laughlin, 2013). Fathers and grandparents were especially important sources of care for young children, particularly for those whose mothers are employed full time.

Organized child care facilities reflect a variety of philosophies about the care of young children, wide differences in curriculum, and a wide range of physical settings. As opposed to the public schools where there are state standards and regulations about the curriculum, time and amount of instruction, and certification of teachers, the U.S. approach to the care of infants and toddlers is highly variable. Whatever arrangements a child's parents can patch together seem to be acceptable. However, most early childhood experts agree that there are markers of quality care that have an impact on children's daily experiences as well as on their long-term cognitive, emotional, and social development. These markers include:

- Advanced training in the field of child development and early childhood education for the caregivers
- A small caregiver-to-child ratio and smaller group size
- A safe, clean environment
- Sensitive, developmentally appropriate interactions between caregivers and children
- Strong, respectful, positive relationships with children's families (Honig, 2012; Watson, Koehn, & Desrochers, 2012)

Table 6.3 lists the 10 standards for accreditation by the National Association for the Education of Young Children. This list provides an idea of what families might look for in trying to evaluate whether a center is likely to support positive developmental outcomes for their child. The question of how to evaluate the quality of child care and its relationship to child outcomes is not as obvious as one might think. At least four dimensions need to be considered: (1) What is the definition of quality and how is it measured? (2) What is the child's exposure to this care? For example, how many months and for how many hours per day are the children in care? (3) Who are the children in question? For example, how old are the children? Are they from low-resource families? Are they in multiple care arrangements? (4) What specific outcomes are being measured?

Table 6.3 NAEYC Standards for Accreditation of Quality Child Care Centers and Preschool Programs

Standard	Definition
1. **Relationships**	The program promotes positive relationships among all children and adults, and encourages each child's sense of individual worth as well as belonging to and contribution to the community.
2. **Curriculum**	The program implements a curriculum that promotes learning and development in social, emotional, physical, language, and cognitive domains.
3. **Teaching**	The program uses developmentally, culturally, and linguistically appropriate teaching approaches that recognize differences in learning styles, needs, interests, and backgrounds to help all children learn.
4. **Assessment of Child Progress**	The program is informed by ongoing systematic, formal, and informal assessment within the context of reciprocal communications with families and sensitivity of cultural contexts. The assessments are helpful to guide curriculum planning, to tailor instruction to children's strengths and needs, and to identify children with developmental disabilities in order to ensure that they receive appropriate services.
5. **Health**	The program promotes nutrition, safety, and health.
6. **Teachers**	The program employs and supports a teaching staff with the educational qualifications, knowledge, and professional commitment needed to promote children's learning and development and to support families' diverse needs and interests.
7. **Families**	The program establishes and maintains collaborative relationships with each child's family, being sensitive to family composition, language, and culture and striving to create bonds of mutual trust and respect.
8. **Community Relationships**	The program establishes relationships and uses resources in the children's communities to support program goals.
9. **Physical Environment**	The program has a safe and healthy environment including both indoor and outdoor facilities, equipment, and materials to support learning and development.
10. **Leadership and Management**	The program effectively implements policies, procedures and systems that support staff, fiscal management, program delivery, and compliance with licensing regulations.

Source: Adapted from NAEYC, 2016, The 10 NAEYC Program Standards.

Assessments of child care's effects on young children generally focus on intellectual abilities, socioemotional development, and peer relations. Research has tended to emphasize the impact of child care on the children of families living in poverty because they are at a higher risk for school failure, illiteracy, and subsequent minimal employment or unemployment, even though they are less likely to be enrolled in center-based care than families with more resources. Many studies focus on Head Start—a federally funded early childhood program that has a complex mission, including education, health, mental health, and family support. However, not all child care programs have the same educational emphasis or developmental curriculum as Head Start. Many studies that investigate the impact of child care do not systematically control for the differences in program focus, services, and hours of service that exist among public and private child care and preschool programs.

Efforts to assess the impact of early child care arrangements on subsequent development are often discussed as causal relationships (e.g., participation in quality early child care results in cognitive benefits). However, these causal statements should be treated cautiously. About 18 percent of young children experience a combination of care arrangements including parental and family member care as well as center-based and nonrelative care, and these arrangements may change from year to year. Experiences with multiple care arrangements and frequent changes in arrangements have been found to be associated with behavioral difficulties even when the settings are of good quality (Morrissey, 2009). The quality of care a child experiences can be assessed, but the many factors that might account for why some children are in high-quality care and others are in poor-quality care, or why some children are in care for many hours a day and others are in care for few hours a day cannot be fully measured or controlled. As a result, it is best to think of studies that evaluate the impact of early child care arrangements as associational rather than causal.

The Impact of Child Care on Intelligence, Cognition, and Academic Achievement

Results of a growing body of research suggest that the effect of quality child care on toddlers' cognitive development is positive but modest (Auger et al., 2014; Ludwig & Phillips, 2007). Data from model programs show that quality child care contributes to intellectual achievement, as reflected in higher IQ scores, both during the preschool years and during the first grade (Burchinal et al., 2000).

Because of the questionable validity of IQ scores for very young children and for children from various racial and ethnic subgroups, the focus on IQ as an indication of program impact may be inadequate. Thus, studies have focused on more specific competencies such as language ability, pre-reading and pre-writing skills, vocabulary, cognitive problem solving, and motivation for school and school achievement as evidence of the long-term impact of child care on intellectual development (Love, Chazan-Cohen, Raikes, & Brooks-Gunn, 2013). Studies of participation in Head Start or Early Head Start (a program for infants to age 3) find initial cognitive benefits in vocabulary, reading, math, and general school readiness. However, by early elementary school, children who were in control or comparison groups were performing at about the same level as those in the Head Start interventions. Certain subgroups of children may benefit more from participation in high quality Head Start programs, especially those whose mothers are recent immigrants, where English is not their primary language spoken at home, and whose mothers have not had much education prior to immigration (Cooper & Lanza, 2014; Love, Chazan-Cohen, Raikes, & Brooks-Gunn, 2013).

Even studies that did not find lasting cognitive advantages in elementary school found evidence for later benefits in school engagement, school completion, attitudes toward learning, and health. For example, children who attended center-based care in pre-kindergarten were less likely to be chronically absent in kindergarten (Gottfried, 2015; Puma et al., 2012).

The National Institute of Child Health and Human Development (NICHD) began a longitudinal study of the effects of early child care in 1991 (National Institutes of Health, 2000). The primary aim of the study was to learn what impact child care has on developmental outcomes above and beyond the influence of family and home environment. In this study, 1,300 children under 1 month of age and their families were identified as participants from 10 sites across the United States. The study followed children into early adolescence, ages 14 and 15. Families varied by race, income, family structure, mother's education and employment status, and the number of hours children spent in nonparental care. The quality of care was measured with a focus on caregiver interactions that are expected to promote positive emotions, social competence, and cognitive and language skills. For more detailed information about this national longitudinal study, look for the SECCYD study on the NICHD website.

Findings from this research suggest that family variables were *more important* predictors of a child's development than the quality of child care in infancy, toddlerhood, and even in middle school. "Higher levels of parenting quality predicted greater levels of tested reading, math, and vocabulary achievement in fifth grade, and lower levels of teacher-rated externalizing problems and conflict and high levels of social skills, social-emotional functioning, and work habits in the sixth grade" (Belsky et al., 2007, p. 693).

However, there were some benefits of participation in quality child care. After all the family factors were taken into account, the quality of language stimulation directed to the child in the child care setting made a significant additional contribution to children's language and cognitive competence. Children in higher quality care had higher scores on measures of cognitive development, language, and school readiness (National Institutes of Health, 2000; NICHD, 2006).

Follow-up studies have found evidence of long-term consequences of exposure to early child care. By the sixth grade, a positive relationship was observed between experiences in quality care and measured vocabulary (Belsky et al., 2007). By age 15, there was continued evidence of a benefit to high-quality care as measured in adolescents' academic performance (Vandell et al., 2010).

For children from low-income families, experiences in high-quality child care can partially offset the negative associations between poverty and subsequent math and reading skills. High-quality child care proved to be a benefit with regard to school readiness at age 3, which was then strongly associated with higher scores in measures of math, reading, applied problem solving, and language skills in grades 5 and 6 (Dearing, McCartney, & Taylor, 2009). In an Australian sample, a positive relationship between center-based care providers and young children was found to improve their vocabulary and reduce behavior difficulties, especially for children from low-income families (Gialamas et al., 2015).

In addition to test score benefits, children who have participated in model programs and Head Start are less likely to be placed in special education classrooms or to be held back a grade. These advantages are of significance in thinking about the tradeoff in costs and benefits of providing early educational experiences to children at risk of school failure (Ludwig & Phillips, 2007).

The Perry Preschool Project, a model program that has carried out extensive longitudinal research on its participants, has documented a number of indications of academic success. In the mid-1960s, 123 African American children from very-low-income families were selected to participate in this program. They were randomly assigned to a quality preschool intervention or to no preschool. At age 19, children who had attended a quality preschool program had higher grades, fewer failing grades, a more positive attitude toward school, and a higher literacy rate than a comparable group of young adults living in poverty who had not participated in a quality child care program (Schweinhart et al., 2005; Schweinhart & Weikart, 1988). Most (95 percent) of those who had participated in the study were re-interviewed at age 27. The group that had the preschool experience continued to show evidence of the benefits of their early childhood education. Those who had attended the quality preschool were 30 percent more likely to have graduated from high school or received their GED. They were four times more likely to be earning $2,000 or more per month, and three times more likely to own their own homes (High/Scope, 2003).

The Impact of Child Care on Social Competence

Quality care is also associated with higher levels of social competence, self-esteem, and empathy. Children who interact positively with adults in their child care settings are more likely to continue to interact positively and comfortably with their teachers and classmates in the elementary grades. Children who experience frequent, high quality interactions with their care providers at ages 2 and 3 are better able to focus their attention and regulate their emotions when they are in early elementary school. Especially for low-income children, frequent positive interactions with care providers over longer periods of time are associated with fewer behavioral problems in the elementary grades (Burchinal, Magnuson, Powel, & Hong, 2015; Gialamas et al., 2014).

Some studies have found that children with more hours of child care experience are less compliant with their parents' wishes than children who have not been in day care. The study conducted by NICHD helps explain these findings. The more time children spent in nonmaternal care, the less responsive mothers were to their children at 15 and 36 months, and the less affectionate the child was to the mother at 24 and 36 months (NICHD Early Child Care Research Network, 2002). These findings were strongest for children who were in low-quality care for the longest time periods. Even when children were adolescents, the consequences of experiences in poor quality care and long hours of care continued to be observed. By age 15, the more hours a child spent in nonfamily care as a toddler, the more they were observed to have difficulties controlling their impulses as an adolescent (Vandell et al., 2010). However, this relationship is moderated by parental sensitivity. Over the years from preschool to adolescence, children who have spent long hours in poor quality care are more likely to be observed as impulsive and as having problems with behavioral control when they also have parents who demonstrate insensitive care (Burchinal, Lowe Vandell, & Belsky, 2014).

Some children are more affected by the quality of their early child care experiences than others (Pluess & Belsky, 2010). Children who were characterized as having a difficult temperament in infancy, especially high levels of negativity and irritability at 6 months, were compared to children who were characterized as low in negativity at 6 months. In sixth grade, these two groups of children were rated by teachers on behavior problems and teacher–child conflicts. For the children who had low levels of negativity, there was no relationship between their experiences in high- or low-quality child care and the way teachers rated their behavior in sixth grade. For the children who had high levels of negativity as infants, the experiences in high- or low-quality child care made a big difference. If the children who had a more difficult temperament also experienced low-quality child care in toddlerhood, they had many more behavior problems and teacher–child conflicts. If the children who had a more difficult temperament were in high-quality child care, they had fewer behavior problems and teacher conflicts than the low-negative children, even those who had been in high-quality care. When evaluating the long-term consequences of early child care experiences, it is important to take into account variations in children's susceptibility to environmental conditions.

Quality child care also has an impact on peer relations. Children benefit from opportunities to interact with a variety of peers in settings where adults are readily available to help them make choices and resolve differences. The quality and complexity of social play are especially enhanced when children remain in the same child care setting rather than moving from one arrangement to another. In stable conditions, toddlers, whose verbal skills are limited, expand their strategies for coordinating their play with others and for exploring shared fantasies. Children who are growing up in difficult and impoverished life circumstances are especially likely to benefit from stable, consistent caregiving practices where they can form a secure attachment to the caregivers and experience calm, friendly interactions with peers (Ritchie & Howes, 2003). Long-term benefits for peer relations were observed for the participants of the Perry Preschool Project when, at age 19, they were more likely to report that they provided help to their friends and family than were comparison participants, but less likely to volunteer without pay for community service (Schweinhart & Weikart, 1988; Schweinhart et al., 2005).

Few of the evaluations of model programs or Head Start have addressed long-term social consequences. However, results from the Perry Preschool Project showed that by age 19, fewer of the children studied had committed delinquent acts or had been processed by the courts, fewer had been on welfare, and more had been employed (Barnett, 1996). In the follow-up at age 27, those who had been enrolled in the quality preschool program were less likely to have been arrested for drug dealing, men had been married longer, and women were more likely to be married and less likely to have had a child out of wedlock (High/Scope, 2003).

Susan Woog-Wagner Science Source/Getty Images

In quality child care, the learning environment combines positive social interactions with many opportunities to foster children's natural curiosity. Armed with their magnifying glasses, these boys bring a new sense of wonder to their observation of a snail.

Child Care and Physical Activity

Concerns are being raised about the need for young children to have more physical activity in their daily routine. According to the U.S. Office of Disease Prevention and Health Promotion, children should have at least 60 minutes of moderate to vigorous physical activity a day (ODPHP, 2016). Vigorous physical activity contributes to aerobic capacity as well as muscle and bone strength. For toddlers and preschoolers, health experts suggest at least 30 minutes of adult-guided activity and 60 minutes of free-play activity daily. Toddlers should not be sedentary for more than 60 minutes at a time except when they are asleep (KidsHealth, 2014).

Given these recommendations, researchers have been examining the amount and quality of physical activity among toddlers and preschoolers in various types of early child care. Children who are in some type of child care setting are typically more physically active while they are at their center or preschool than when they are at home (Hesketh, Griffin, Simon, & van Sluijs, 2015). In a study of physical activity in 35 U.S. centers, children were observed to spend an average of 9 minutes per waking hour in moderate to vigorous physical activity (Henderson, Grode, O'Connell, & Schwartz, 2015). The strongest predictors of frequent physical activity in centers include encouragement for free play, time spent in outdoor play, suitability of the indoor play spaces for large muscle activity, and encouragement from teachers for active play. We think of toddlers as naturally active. However, observational research suggests that children in care will not get the amount of vigorous physical activity they need unless there is focused attention on motor development as a part of the curriculum and the design of the environment.

Benefits Associated with Head Start

Head Start is more comprehensive than most preschool or child care programs. As a result, it has the potential for a broader range of benefits to children and families than other programs. The Head Start program standards include requirements for the staff to provide children and families with comprehensive services related to health and nutrition. Staff must assist parents in using available resources for immunization; regular checkups; screening for health, vision, and behavioral problems; and regular preventive dental care (U.S. Code of Federal Regulations, 2002, 2015). In 30 studies that reported on the health impact of Head Start, the data showed that participating children are more likely to get a wide variety of examinations and assessments covering medical and dental health, speech and hearing, vision, and nutrition. Because Head Start provides meals, young children in the program have a much higher daily nutritional intake than similar children who are not in the program (Zigler & Styfco, 2004). All of these opportunities allow a direct response to young children's physical needs when their parents may not be aware of emerging problems or are unsure how to address them. The following health benefits have been documented through systematic research (NHSA, 2016):

- Mortality rates for 5- to 9-year-old children who had attended Head Start are 33 to 50 percent lower than the rates for comparable children who were not enrolled in Head Start (Ludwig & Miller, 2007).
- Head Start children are more likely to receive dental checkups and have healthy eating patterns than nonparticipants (Lee et al., 2013).
- Head Start children have lower Body Mass Index (BMI) scores and are less likely to be overweight compared to children in nonparental care (Lee et al., 2013).
- Preschool age children who were obese, overweight, or underweight and who participated in Head Start had a significantly healthier BMI by kindergarten entry than control children (Lumeng et al., 2015).
- Head Start improves adult health status for graduates; they are 7 percent less likely to be in poor health as adults than their siblings who did not attend (Deming, 2009; Johnson, 2010).
- As adults, Head Start graduates are 19 percent less likely to smoke than their siblings who did not attend,- and savings from reduced health costs are equal to 36 percent to-141 percent of the program costs (Anderson et al., 2010).
- The Head Start Trauma Smart program integrates training for program staff and parents, support groups, classroom consultation, and individual child treatment to support children who have experienced trauma; the program has decreased children's need for special education services (Holmes et al., 2015).

As an additional benefit, Head Start has a positive impact on families and communities. A key area of Head Start programming is parent education and parent involvement. Parents whose children are in Head Start are less likely to spank their children and spend more time reading to their children than parents whose children are in other kinds of child care programs (Puma et al., 2005). Head Start has provided education, training, and career development for millions of parents and community members. It has mobilized over a million community volunteers to assist in Head Start classrooms, and most of these volunteers were once Head Start or Early Head Start parents. Head Start has created hundreds of thousands of jobs, the majority of which are held by people who live in the low-resource communities where the programs are located. Thus, Head Start contributes to the advancement and engagement of community adults, drawing on their talents to contribute to the quality of education in their communities (NHSA.org, 2016).

Directions for the Future of Child Care in the United States

In his 2013 State of the Union address, President Obama proposed creating a universal pre-kindergarten program. The program would include several components:

> "financial assistance to help parents pay for infant and toddler care; additional investment in the Early Head Start programs; and a proposal to partner with states, matching their investments dollar-for-dollar, with a goal of subsidizing preschool based on income" (Cohn, 2013). Prekindergarten would not be required for all children, but it would be accessible and affordable for all.

Given the current political climate, the probability of any immediate action on this proposal is low. States vary widely in their support of pre-kindergarten access. There are 50 programs in 40 states plus DC that offer state-funded pre-kindergarten programs. Four-year olds are the primary target, making up 86 percent of the children enrolled. At present, these programs are far from universal. If we consider children enrolled in state-funded pre-kindergarten, Head Start, and special education preschool programs, 41.5 percent of 4 year olds and l4.5 percent of 3 year olds are enrolled (Barnett et al., 2015).

Concerns about the need for affordable, quality child care are expressed by parents who are in the labor market as well as by those who would like to be in the labor market. Worries about child care arrangements are a significant source of stress for working parents. Concerns about child care continue throughout toddlerhood and well into the elementary school years when children need adult companionship and supervision before and after school hours. Services for certain groups, including children with disabilities, those whose parents have evening work schedules, children who are ill, and those who need year-round programs, are in short supply. Many families living in low-income communities do not have access to quality care.

National welfare policies add pressure on the need for affordable, quality child care services. In the past, for example, Head Start programs, which have been an important resource to children in low-income families, have not offered full day care. However, because mothers of young children who were previously receiving welfare benefits are required to enter the labor market, they need to find full day care for their children. Consider the dilemma of a woman who was trying to locate quality care for her child:

> I called child care agencies. . . . And I interviewed all the people they [the state] gave me with licenses. I sat in some of the places for quite a while. I saw drugs being sold in and out of those places. I found one place I thought my daughter would be secure. She was sexually abused. I think that was the thing that really gave it to me then: I quit my job and went fully back on the welfare system. (Scarbrough, 2001, p. 267)

Quality, affordable child care is one of the primary resources that single parents rely on in order to stay off welfare. Without some form of child care subsidy, women cannot support themselves and their families on what they are typically able to earn in jobs that pay a minimum wage. Even with such a subsidy, the likelihood of finding a high-quality setting is low, and the risks to toddlers of spending time in a poor-quality setting are great.

FURTHER REFLECTION *Imagine that you have to decide about child care arrangements for your child. Given what you have read about the developmental tasks and the psychosocial crisis of toddlerhood, what features of the child care arrangement are most important for optimizing development for your child?*

Given what you know about the diversity of U.S. families and the current economic and political environment, what do you think are the most likely trends for child care arrangements in the coming 10 years?

CHAPTER SUMMARY

OBJECTIVE 1 Describe the expansion of motor skills during toddlerhood, and explain their importance for the child's capacity to explore the environment and to experience opportunities for mastery.

The developmental tasks of toddlerhood support children's ability to express themselves through action, language, fantasy, and self-directed goal attainment. The tasks of toddlerhood all contribute to a child's ability to participate in and feel a sense of connection to the social group. Locomotive skills heighten toddlers' sense of mastery and expand their boundaries of experience. Advanced motor skills highlight the dynamic interaction of brain development, physical growth, opportunity, and practice.

OBJECTIVE 2 Summarize the accomplishments in language development and outline the features of the language environment that support communicative competence.

Language is both a tool for the expression of feelings and concepts and a primary mechanism of socialization. Communicative competence relies on both genetically-based capacities for symbolic representation and exposure to a language system. Certain language skills are more vulnerable to the timing of exposure than others, illustrating an important feature of plasticity. Toddlers' use of language gives us clues as to their cognitive and social development. Through language, children gain access to worlds of information, learn new strategies for the control and expression of their impulses, and form meaningful connections with others.

OBJECTIVE 3 Explain the development of fantasy play and its importance for cognitive and social development.

The emergence of fantasy provides toddlers with an internal, personal form of symbolic representation. Fantasy allows a pseudomastery in which barriers are overcome and the limitations of reality are less important. In fantasy, toddlers experiment symbolically with objects, roles, and events that occur in their daily lives. Conflicts can be acted out, and pretend solutions can be found. Fantasy may be enhanced by language, but it thrives even in the absence of words.

OBJECTIVE 4 Examine the factors that contribute to the development of self-control, including impulse management and goal attainment.

Efforts at self-control—both impulse regulation and self-directed goal attainment—begin in toddlerhood and continue through life. Temperamental differences in negative emotionality, anger proneness, fearfulness, and activity level can all influence the child's ability to achieve self-control. At the same time, these differences are shaped by parenting practices that help or disrupt children's capacities for regulation. Self-control is a foundational capacity that predicts subsequent adaptive functioning in school, peer relationships, and moral behavior.

OBJECTIVE 5 Define the psychosocial crisis of autonomy versus shame and doubt, the central process of imitation, the prime adaptive ego strength of will, and the core pathology of compulsion.

The psychosocial crisis of autonomy versus shame and doubt reflects the child's needs for self-expression and mastery in the context of their social group. Young children develop individuality by exercising the skills that develop during toddlerhood. Self-doubts result from repeated ridicule, shame, and failure. The adaptive ego quality of will, directly linked to self-directed goal attainment, emerges in a positive resolution of this crisis. In the context of shame and doubt, the child is likely to rely more and more on compulsive, ritualized behaviors.

Autonomy and individuation are given different values across cultures. Within the context of parent–child relationships, children learn in what ways they are expected to become self-sufficient and self-expressive and to what extent they are expected to fit in or blend in with others. Toddlers are avid observers, imitating and incorporating parental behaviors and values into their own routines. Parental interaction, acceptance, and discipline all contribute to a child's emerging sense of individuality and connection.

OBJECTIVE 6 Evaluate the impact of poverty on development in toddlerhood.

Living in poverty poses challenges to optimal development during the prenatal period and infancy, and these risks continue throughout toddlerhood. Poor nutrition, lack of health care, harsh or neglectful parenting, and exposure to chaotic neighborhoods can all influence the direction of cognitive development, emotional regulation, social competence, and sense of control. Growing up in a very poor community increases the likelihood that parents will be psychologically unavailable or will use harsh, restrictive disciplinary strategies that produce shame or unexpressed rage in their young children.

OBJECTIVE 7 Apply a psychosocial analysis to the topic of child care, emphasizing the impact of the kind of care and the quality of care on development during toddlerhood.

Increasing numbers of young children are being cared for in group settings. The impact of child care depends largely on the quality of the personnel, the nature of the program, and an appropriate physical environment. The most important predictor of children's social and cognitive maturation is the quality of parenting they receive. Nonetheless, many studies find a consistent relationship between quality child care and cognitive development, especially in the area of language acquisition. Whereas the contributions of quality child care are modest but positive, the consequences of poor quality care can be seriously disruptive. A major policy concern is how to expand affordable, high-quality care for those families that need it.

CASEBOOK

For additional case material related to this chapter, see the case of "Little Raymond," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman, pp. 77–80. The case illustrates ways in which a toddler uses language and fantasy to cope with frustration when his mom's boyfriend interferes with his play.

Claude in Blue, 1950/© 2011 Estate of Pablo Picasso/Artists Rights Society (ARS), New York

Starting school brings an expansion of the child's social world: encounters with new adults and peers, new social norms, higher expectations, and new information. Each of these changes has an effect on the child's self-concept.

LEARNING OBJECTIVES

1. Describe the process of gender identification during early school age and explain its importance for the way a child interprets experiences.
2. Summarize the process of early moral development, drawing from theories and research to explain how knowledge, emotion, and action combine to produce internalized morality.
3. Analyze changes in the self-theory, with special focus on the theory of mind and self-esteem during the early-school-age years.
4. Describe the features of peer play, including group games, media play, and friendship in the early-school-age years.
5. Explain the psychosocial crisis of initiative versus guilt, the central process of identification, the prime adaptive ego quality of purpose, and the core pathology of inhibition.
6. Define the concept of school readiness, and analyze its relation to the developmental tasks of early school age. Summarize obstacles that may prevent children from being able to adapt and learn in the school environment.

Chapter Summary

— **CASE STUDY** Gloria Remembers Being 5 Years Old —

Gloria Johnson-Powell recalls growing up, a middle child among five siblings, in an African American family living in a predominantly white neighborhood in Boston. As an adult, she studied medicine, became a psychiatrist, and joined the faculty at UCLA and then Harvard medical schools. Going back to live in Boston after many years away, the conflicting memories of her early years stimulate a reconstruction of her view of self in society as a small child.

Going to nursery school was a major event for me, but I'm not certain if all of my siblings had the exciting experience of going to St. Mark's Congregational Church on Townsend Street for nursery school. It was only a block away from our house on Elbert Street and, on some occasions, I was allowed to walk that block while my mother stood at the corner and watched. I can remember feeling so grown-up, almost as big as the big kids—Barbara and Alice (*her older sisters*).

I can remember that as early as 5 years old I decided that I did not want to grow up. The glimpses into the adult world that I perceived were too complex and troubling for me. As a child I had minimal responsibilities. I could think what I pleased without any contention, and was free to play, to dream, and to learn at will. I even had my own closet where I would go to play or to daydream, but most often to read without disturbance. I loved the cocoon in which I lived and had no desire for any transitions except my promotions in school. Indeed, my scholarly pursuits became the security cloak to protect me from having to enter the real world where I felt I could not compete with my dark skin and my long, very thin body. Besides, black was not beautiful in a predominantly white world. (Johnson-Powell, 1996, p. 56).

CASE ANALYSIS Using What You Know

1. Gloria recalls with some pride being able to walk by herself from home to school. Do you have any similar memories of your own sense of initiative and purposeful behavior in the ages 4–6? Any recollections of other activities that made you feel "grown up"?
2. Gloria had a special private place where she felt safe to imagine and to read. Do you recall any similar spot where you felt protected from the demands of the adult world? Explain why a child might need this kind of place.
3. Gloria reflects on certain aspects of her self-concept, especially her appearance, her race, and being the "little sister." Try to recall the features of your own self-concept that were taking shape at this age. Were some a source of shame? Were some a source of pride?
4. Analyze this case from the perspective of the biological, the psychological, and the societal systems. How does each of these systems contribute to the sense of self that is emerging for Gloria in her early childhood?

The period of early school age brings children face to face with new and complex socialization forces. By the age of 6, virtually all children in the United States are enrolled in school. Before they start kindergarten, most children have school-like experiences in child care, nursery school, early childhood programs, or prekindergarten to prepare them for the environment and demands of school. School brings new information and experiences, new opportunities for success and failure, and new settings for peer group formation. School is a source of influence on the child beyond the family. Beliefs and practices followed at home may be challenged by teachers or classmates. Parents' personal hopes and aspirations for their children may be tempered by the reality of their children's school performance. Although the law requires children to attend school, many are found to be lacking the cognitive, emotional, and/or behavioral maturity to do well. This leads to the question of what it takes to be ready to go to school.

Most early-school-age children exhibit wide-ranging curiosity about all facets of life. "How does this work?" "Why is that the rule?" "Why can't I do that?" The child's self-concept is transformed in coordination with exposure to new socialization voices. In addition to family and school, the peer group, neighborhood, and television all influence children's self-concept during early school age. Once children become aware of alternatives to their own families' rules and patterns, they may begin to question familiar notions. The press toward *independence of action* seen in the toddler is now accompanied by a new *independence of thought* in the early-school-age child. ●

Developmental Tasks

During the early-school-age period, between the ages of 4 and 6, children are constructing an overview of how their interpersonal world is structured and where they fit in. They are devising a scheme for self in society. Because children's life experiences are limited and they are still highly impressionable, the nature of this initial worldview is likely to be very compelling, permeating their outlook in the years ahead. The lessons from early childhood about what it means to be a good person, to be a good boy or girl, man or woman, to be cherished or despised are established at a deep emotional and cognitive level. These ideas are intertwined with feelings of being safe, loved, and admired or neglected, rejected, or abused. As a result, the basic beliefs about oneself and others that are formed at this time are often difficult to change.

In this chapter, four developmental tasks are discussed that contribute to a child's capacity to construct a worldview: gender identification, moral development, self-theory, and peer play. The topic of gender identification includes a discussion of the neurobiological, physical, cognitive, emotional, and social domains as they become integrated into an early scheme for thinking of oneself as male or female. Issues of right and wrong surface constantly as a result of the child's newly acquired abilities for independent thought and exposure to a wide range of social influences. These experiences provide the basis for early moral development. The self-concept expands markedly during early school age. This developmental task centers on the acquisition of a personal self-theory that becomes increasingly

pio3/Shutterstock.com

In early school age, children's worlds expand as they spend more time playing with friends, going to school, and exploring their neighborhoods.

complex because it is being stimulated by many new social influences. Accompanying the development of the self-theory is the development of a set of complex feelings about self-worth called self-esteem. A fourth area involves new levels of participation in friendship and peer play. Through the process of learning the rules and playing cooperatively with others, children begin to form meaningful friendships and mental representations of ways of participating in groups.

Gender Identification

OBJECTIVE 1 Describe the process of gender identification during early school age and explain its importance for the way a child interprets experiences.

Every human society has patterns of organization based partially on gender. Male and female individuals are often assigned different roles, engage in different tasks, have access to different resources, and are viewed as having different powers and attributes. The specific content of these gender roles varies from one culture to another. As children form their concept of gender identity, they must integrate their own physical experiences, knowledge, and observations with the socialization messages coming to them from parents, siblings, peers, and other salient voices of the culture.

In this and other discussions of **gender identification**, you will want to differentiate among three concepts: sex, gender, and sexual orientation. **Sex** refers to a person's biological maleness or femaleness, which is determined by chromosomal information. An infant's external genitalia are typically used as the evidence to determine sex. In most cases, the chromosomes and the hormones that are produced in the prenatal period converge to produce an unambiguous sex. However, there are exceptions. The term **intersex** is used to refer to conditions in which a person's external genital anatomy does not match their genetic chromosomal status. Researchers are discovering that biological sex is more of a spectrum than the generally accepted dichotomy between male and female would suggest. Recent studies have identified 25 genes that contribute to sexual diversity. The expression of these genes may be observed in genital abnormalities at birth, but in some cases they are not recognized until puberty, or when problems with infertility arise in adulthood. An estimated 1 in 100 people have some type of intersex condition, resulting in a growing advocacy for a more differentiated view of sex than the current social and legal systems support (Ainsworth, 2015).

Gender refers to the integrated cognitive, social, emotional, and behavioral patterns associated with being a boy or girl, man or woman in one's culture. In childhood, gender identification includes learning to identify oneself as a boy or girl in one's family, friendship group, and community; learning and internalizing the community's expectations for how boys and girls ought to behave; and sensing how well one meets the social expectations for a boy or girl. Some children, described as transgender or gender nonconforming, demonstrate mannerisms, choice of clothes, activity preferences, or use of self-referents that conflict with social expectations associated with the sex they are were assigned at birth (Lev & Alie, 2012; Olson, Key, & Easton, 2015).

Sexual orientation refers to one's preference for and attraction to sexually intimate partners. Sexual orientation can be thought of as ranging along a continuum from exclusive attraction to the same sex to exclusive attraction to the other sex. Four sexual orientations discussed in the literature are *heterosexual*, *homosexual*, *bisexual*, and *asexual* (American Psychological Association, 2008). In the acronym LGBTQ, L stands for Lesbian (females whose primary sexual attraction is other females); G stands for Gay (males whose primary sexual attraction is other males); and B stands for Bisexual (females or males who are attracted to both females and males). T stands for Transgender and refers to one's gender, not one's sexual orientation. Q may stand for Queer or Questioning. It is an umbrella term to reflect that the person identifies as outside the societal norm, but does not want to be constrained by a specific label. The term Queer provides a link to a community of people who accept gender and sexual diversity.

> Why does it matter how I'm different, when I'm different, or why I'm different? Just let there be a place in this society for difference—of any sort—and accept me any way that I am or am not. Accept me as queer. (PFLAG, 2016)

Sexual orientation is not a primary topic of discussion in this chapter. However, it is important to appreciate the distinction between sexual orientation and gender identity, particularly in this chapter because of questions raised in research on the relationship of the sexual orientation of parents to the gender identity of their children.

— **CASE STUDY** Gender Identification in Early Childhood —

Lee, a mother of six children, recalls with warmth and humor her early childhood years growing up in New Mexico in the 1920s and 1930s.

I was born in the southern part of New Mexico in Ruidoso. The town was up in the pines in the mountains and was mostly just a main street that followed the river. There was a meadow on one side of the river with a lot of Indian arrowheads and shards and the biggest grasshoppers in the world. I used to go catch grasshoppers and find arrowheads, and my cousin Bob and I would wander around by ourselves.

My father was a carpenter and my mother had planned to be a nurse until she stopped and got married. I think my father must have really wanted a son because I was quite a tomboy and grew up as his only son. I helped him dig and move rocks instead of learning how to cook and sew. We had a large family, uncles and aunts and a grandmother and great aunt, with houses right next to each other and big, traditional holiday dinners with everybody there.

My cousin Bob was two years younger than I was and we were inseparable. . . . He was a rough, tough little kid. We ran around without coats in the winter and hardly ever got sick. . . . It was almost like two boys because we used to go to the river and fish with our hands and churn the fish over a little fire and try to eat it. We just grew up like little wild things. My parents expected me to be on the premises by nightfall, but that was about it. We played cowboys and Indians with the other kids in the neighborhood, and we never played with girls at all; they were really something to be scorned. But he was allowed to cuss and have good tantrums that I wasn't allowed to have.

My mother always provided books and she would tell stories about Huckleberry Finn. The river in our town was much too small for a raft; it was rocky and was just a stream, but we'd pretend rafts and imagine running away. One time I got tied up on an Indian raid and left there, and I was too stubborn to call for help, so I was there past supper time and my mother found me and brought me in. I was always tearing up my clothes, and my mother was always tearing me up about that. I think she would have liked to have a daughter. It wasn't until my sister Barbara was born that she had a daughter. Barbara had long curls and was pretty feminine. That way mother had the daughter to play with and daddy had the son and everything was all right.

CASE ANALYSIS Using What You Know

1. Summarize the aspects of the formation of gender identification that are captured in this narrative.
2. Describe the mental representations of her mother and father with which Lee may have identified.
3. Analyze the role that the context of the physical environment may have played in Lee's experiences of gender identification.
4. Hypothesize about factors that contributed to Lee's preference for rough-and-tumble play. What role do you attribute to her desire to be "the son" for her father? What role do you attribute to her temperament and other aspects of her personality?
5. From what you have read, and drawing on your own experiences, imagine how Lee's gender identification at this period of her life might influence her later relationships with male and female peers and her capacity to form intimate relationships in later adolescence or early adulthood.

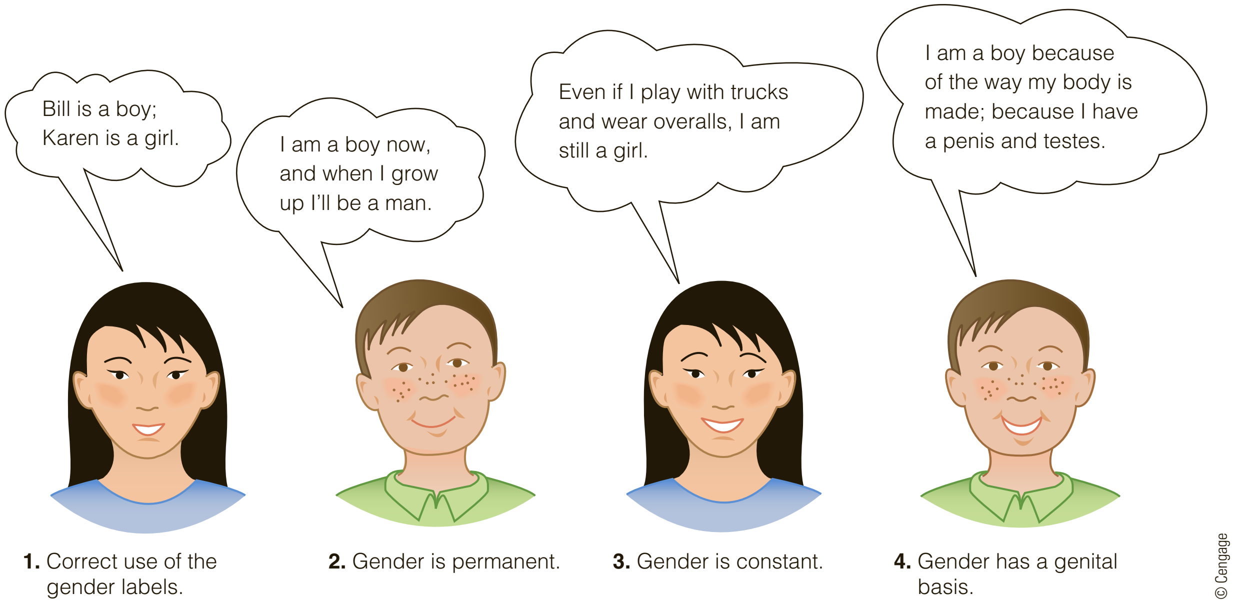
A Framework for Thinking About Gender Identification

Our goal in the discussion that follows is to explore how young children begin to understand gender. Gender is a dimension of the self-concept, an organizing principle of social life, and a guide to behavior. We do not expect a lifetime's work on gender identity to have been completed by 6 years of age. During this stage, however, significant cognitive, emotional, and social changes make gender more meaningful and highlight the relevance of gender for a child's overall self-concept. Gender is among the very early social categories upon which children base inferences about others. Establishment of gender identification links a child to others of their gender reference group and influences their interests, preferences, and social interactions (Ruble et al., 2004).

Gender identification is a product of the interaction of the biological, the psychological, and the societal systems. Biological factors including brain organization and physical capacities combine with socialization pressures and a child's own understanding of the demands of the situation to create experiences of positive, enjoyable action. In one culture, a 4-year-old girl may feel happy and competent when she is playing with a toy loom, learning to weave as her older sisters and her mother do, while in another culture a 4-year-old girl may feel happy and competent when she is playing pretend school with a friend. These gendered states are emotionally and behaviorally satisfying. They draw on cognitive and motor skills that are well developed for girls and are socially encouraged by adults and peers in the community. As a result, there is a desire to repeat them. Over time, these experiences become increasingly more likely and draw the child into a pattern of gendered interpersonal interactions, play, and learning activities. However, they are not inflexible. A girl who most enjoys playing pretend school with friends can engage in rough-and-tumble play if her male cousins come over for a visit or when her dad comes home from work. As in the case of Lee, a girl can experience rough-and-tumble play as her most pleasurable activity, and still know that she is a girl.

Our analysis of gender identification focuses on four components: (1) understanding the concept of gender, (2) learning gender-role standards and stereotypes, (3) identifying with parents, and (4) forming a gender preference.

Children are actively constructing their gender identity in light of their physical body, unique talents and preferences, socialization messages, temperament, and the gendered behaviors of others (Martin & Ruble, 2010). Children of this age ask a lot of questions about reproductive and sexual topics, take great interest in the nature of household and family roles, and try to figure out how their status as a male or female fits into their self-theory. The outcome of this work will differ from child to child. Most of the literature on gender differences acknowledges that differences within groups of males or females are greater than the average differences between males and females (Hyde, 2005). We believe that these intragroup variations have their origin in the unique ways



Bill is a boy;
Karen is a girl.
I am a boy now, and when I grow up I'll be a man.
Even if I play with trucks and wear overalls, I am still a girl.
I am a boy because of the way my body is made; because I have a penis and testes.
1. Correct use of the gender labels.
2. Gender is permanent.
3. Gender is constant.
4. Gender has a genital basis.

FIGURE 7.1 ▶ Four Components for Understanding Gender

that boys and girls create personal mental representations of gender during the early-school-age period. (See FIGURE 7.1 ▶.)

Understanding Gender

Understanding one's gender involves four components that emerge in a developmental sequence from toddlerhood through early school age (Kohlberg, 1966; Martin, Ruble, & Szkrybalo, 2002): (1) applying the correct gender label to oneself and others, (2) understanding that gender is permanent, (3) understanding gender constancy, and (4) understanding the genital basis of gender (see Figure 7.1). According to this analysis, children create the personal meaning of gender in much the same way that they form other cognitive schemes.

The correct use of **gender labels** is the earliest component of gender identification to be achieved. The recognition of people as male and female is a natural category, much like the recognition of the difference between familiar people and strangers or between people and inanimate objects, as discussed in chapter 5. Even before the abstract categories *male* and *female* are understood, children learn to refer to themselves as boys or girls by imitating their parents. From infancy, parents make continual reference to a child's gender in such statements as "That's a good boy" or "That's a good girl."

As early as 21 months, a majority of infants produce at least one gender label, such as boy or girl. By the age of 2½, children can accurately label other children as boys or girls, and by the age of 3, they can accurately sort photographs of boys and girls. They can also apply gender labels such as *Mommy* and *Daddy*, *brother* and *sister*, and *boy* and *girl* accurately. These verbal labels become useful for guiding a child's attention to important distinctions between males and females (Dunham, Baron, & Banaji, 2008; Dunham, Baron, & Carey, 2011; Gelman, Taylor, & Nguyen, 2004). Once they know these labels, children seek out cues to help them make these distinctions correctly, like hair style, clothes, or body shape. Their attention is directed to the differences between male and female individuals. When children have words or labels for gender categories, they can further understand these categories and their appropriate applications (Nelson, 2012; Waxman & Lidz, 2006). What is more, when children begin to use gender labels, they also increase their gender-typed play, suggesting that the representation of oneself as a boy or a girl motivates and guides their gender-typed behaviors (Zosuls et al., 2009). As children recognize themselves as boys or girls, they begin to feel some affinity for their group. This means a greater liking for girls if you are a girl, or for boys if you are a boy. This is the very beginning of what emerges later as in-group bias.

Understanding **gender permanence** and **gender constancy** emerge somewhat later, usually between ages 4 and 7 (Levy, 1998; Serbin, Powlishta, & Gulko, 1993). Permanence refers to an appreciation that a boy grows up to be a man and a girl grows up to be a woman. One's sex is permanent over time, even though many other things about one might change. Constancy refers to an appreciation that one's sex is unchanged by clothing, hairstyle, play activities, and other day-to-day alterations. Even if a boy puts on a wig and dresses up in a fancy dress, pretending to be a princess, he is still a boy. Even if a girl puts on a helmet and shoulder pads and pretends to be a football player, she is still a girl.

Understanding the **genital basis of gender labels** provides a fundamental context for understanding that gender is permanent and constant. In research involving 3-, 4-, and 5-year-olds, the majority of children who understood the genital differences between the sexes could also tell that a child's sex did not change simply because the child was dressed up to look like a member of the opposite sex. These young children understood that gender is a constant feature of a person, no matter how the person is dressed or whether the hair is long or short. In contrast, the majority of the children who had no knowledge of genital differences were unable to respond correctly to questions about constancy (Bem, 1989).

Gender-Role Standards and Sex Stereotypes

Gender-role standards are cultural expectations about appropriate behavior for boys and girls and for men and women. One might consider these *sex stereotypes*. If you had no information about a person other than whether the person was male or female, what qualities would you attribute to that person? How would you expect the person to behave? Gender-role standards tell us what the culture considers typical and admirable for girls and boys, men and women (Eagly, 2009). For young children, this usually means the kinds of toys, clothes, and activities that would be preferred by boys or girls.

In research on gender-role standards, children are typically asked to identify whether certain activities, occupations, or traits are more frequently associated with male individuals, female individuals, or both. For example, in the *Sex-Role Learning Index*, children are shown drawings of 20 objects traditionally associated with gender roles—10 for the male gender role (such as a hammer, a shovel, and a fire helmet) and 10 for the female gender role (such as an iron, a stove, and dishes). By age 7, most children make a perfect score on this type of test, illustrating that they know how their society links a person's sex to activities or occupations (Beere, 1990; Levy, 1998; Serbin et al., 1993). Knowledge of gender-typed personality traits, such as gentle and affectionate or adventurous and self-confident, emerges somewhat later. In one study of more than 550 children, sixth graders answered about 90 percent of these types of questions correctly (Serbin et al., 1993).

An early-school-age child's knowledge about gender-role standards shapes the child's preferences and behaviors. For example, once children identify certain toys as more appropriate for girls and others as more appropriate for boys, their own toy preferences are guided by these standards. Conversely, when they like a toy that is not obviously sex-stereotyped, they are inclined to think that other children of their sex would like that toy as well (Martin, Eisenbud, & Rose, 1995). One consequence of this gender-typed thinking is that it may limit a child's willingness to play with certain toys and games and therefore reduces the child's opportunities to learn from a variety of play experiences.

One expression of gender stereotyping is a child's rigid insistence on wearing gender-stereotyped clothing. Little girls might insist on wearing skirts or dresses; little boys reject any clothes that have bows, frills, or "girly" designs. One study found that across diverse ethnic groups, the more children positively identified with their natal sex and understood the idea of gender stability, the more likely they were to want to wear gender-stereotyped clothing (Halim et al., 2014).

The nature of parental influences on children's gender role stereotyping is very complex. Some parents believe that boys should be assertive and fight for their rights. Others believe that boys should think carefully about what is right and wrong and guide their actions by reason rather than by impulsive aggression. Each of these sets of parents has a conception of male attributes that is communicated to their sons over a long period. The toys that parents give their children, the experiences to which they expose them, and the activities in which they encourage their children's participation all reflect dimensions of the parents' gender-role standards. By the time children reach school age, they have been encouraged to adopt those standards and may have been shamed or chided for what their parents have viewed as gender-inappropriate behavior. Young girls may be shamed for their assertiveness by being told that they are acting bossy, and young boys may be warned to stop acting like a sissy.

ROB & SAS/Getty Images

Although early-school-age children are familiar with gender stereotypes, they are also likely to be flexible in their gender-role play.

As the cognitive underpinnings related to the concept of gender mature, children form **gender schemes**, or personal theories about cultural expectations and stereotypes related to gender. Children look for clues about gender, seeking information from their social environment about what activities they should or should not engage in ("Boys don't dance," "Girls don't play with trucks," "Pink scooters are for girls; blue scooters are for boys"); whom they should play with; and what information is especially relevant for them as boys or girls. They use this information to organize their perceptions, focus their attention, and interpret information in such a way as to be consistent with their gender scheme. For example, 4-year-old children use information about gender to decide which other children they would like to be friends with (Shutts, Roben, & Spelke, 2013). When young children are placed in a situation where they are uncertain about how to use a certain piece of equipment or when they are trying to understand a new bit of information, they are more likely to turn to an adult of their own gender to get new information (Ma & Wooley, 2013; Martin & Ruble, 2004).

Not all children are equally rigid in applying gender-role standards to themselves or to others. Flexibility in the application of gender-role standards to oneself and others appears to be influenced by both cognitive factors and socialization. Preschool-age children are more flexible than older children. For example, they are likely to see gender-role transgressions (e.g., boys playing with dolls or girls pretending to be firefighters) as more permissible than do older children, ages 6 and 7 (Lobel & Menashri, 1993; Smetana, 1986). Young children who have more advanced abilities to differentiate between moral norms (e.g., telling the truth) and social norms (e.g., saying "please" and "thank you") are also less sex-stereotyped in their play activities and toy choices (Lobel & Menashri, 1993).

Variations in family environments and socialization influence children's thinking about gender-role norms. In most countries around the world, women/mothers are more involved in caregiving activities than men/fathers for both boys and girls. Thus, if children are looking for evidence about gender role stereotypes, it is not surprising to think that they might associate being a female with the caregiving role. Children whose mothers perform nontraditional tasks develop a more flexible attitude, seeing more activities and occupations as appropriate for both men and women (Serbin et al., 1993). However, when looking at how mothers interact with their male and female children, few differences have been observed. One notable exception is that in countries characterized by an overall low level of socioeconomic development, parents were more likely to take their boys outside to play, read to them, and engage them in naming things, counting, and drawing. In these countries, young girls were more likely to be involved in child labor than young boys (Bornstein, Putnick, Deater-Dekcard, Lansford, & Bradley, 2016).

Identification with Parents

The third component of gender identification involves **parental identification**. Identification is the process through which one person incorporates the values and beliefs of another. To identify with someone is to increase one's sense of allegiance and closeness with that person. Through the process of identification, ideals, values, and standards of the family and community are internalized so that they become a part of the individual's own belief system.

During early school age, most children admire and want to be like their parents. Young children are enthusiastic observers of their parents as models, they are emotionally invested in their parents' reactions to them, and they are eager to internalize parental values. Young children integrate parental values and behaviors as part of their gender scheme. When parents have more traditional views about gender, their young children's ideas about gender are more stereotyped, both about themselves and about others (Tennenbaum & Leaper, 2002). Children identify with their parents' gender-related beliefs through conversations that they have about books, movies, and television programs. When parents challenge the gender stereotypes that are portrayed in these media, the children are likely to have a less stereotyped view of gender (Friedman, Leaper, & Bigler, 2007).

Parents can make deliberate efforts to encourage more flexibility in gender-role conceptualization and preferences by deliberately modeling counter-stereotyped activities—fathers making dinner or mothers mowing the lawn—and including more counter-stereotypical comments in conversations with their children (Friedman, Leaper, & Bigler, 2007). Parents can also balance their child's toys and play activities, introducing gender-neutral games and toys, as well as introducing toys and games that may be associated with boys (e.g., playing with toy trucks and cars on a track) and others that are associated with girls (e.g., playing pretend school) (Leaper, 2000).

Parents devise their beliefs and parenting practices out of their own internalized cultural script about gender. So even if they endorse gender flexibility, they may not be able to carry through entirely with their beliefs. For example, many studies focus on how parents talk to their children. The results of this work suggest that mothers are generally both more supportive and more negative with their children—that is, more expressive—whereas fathers are more directive, or task oriented. Furthermore, daughters receive more verbal interaction than do sons, especially from mothers. Finally, fathers are more assertive than mothers, and children are more assertive with their mothers than with their fathers (Leaper, Anderson, & Sanders, 1998). Thus, the family environment is *gendered* through patterns of communication that give children different role models for the behavior of mothers and fathers and provide boys and girls with opportunities to develop different approaches to social interaction.

In addition to the enactment of scripts for how to interact, most adults have deeply held standards about how men and women, boys and girls ought to behave. Consider the following:

> [A family] with three children (5-year-old Dan, 7-year-old Lyle, and 3.5-year-old Amy) in which the mother had always believed that her children should be exposed to all types of experiences, with no distinction indicated between "boy's kind" and "girl's kind." She encouraged her older son's play with dolls. . . . The boys were not allowed to play "aggressive" sports (American football) and were redirected by parents toward ballet and soccer. Yet the mother herself reported being "taken to the limits":
>
> . . . watching her [the mother] play with Amy, the mother was painting Amy's fingernails, Dan asked his mother to paint his fingernails too. "I could only bring myself to paint two [nails]. I knew it was ridiculous, but it just bothered me." (MacKain, 1987, p. 120)

This example illustrates how strongly internalized the standards about gender distinctions can be. Even for parents who want to minimize gender distinctions, some prohibitions or constraints are difficult to disregard (Valsiner, 2000).

The **Applying Theory and Research to Life** box discusses children raised by gay or lesbian parents. The research finds no differences in gender-role behavior, gender identity, or emotional well-being between children raised by heterosexual or homosexual parents.

Gender Preference

The fourth component of gender identification is the development of a personal preference for the kinds of activities and attitudes associated with masculine or feminine roles. Preferences for gender-typed play activities and same-sex play companions have been observed among preschoolers as well as older children (Hoffmann & Powlishta, 2001). Egan and Perry (2001) conceived of gender preference as a combination of gender typicality and gender contentedness. **Gender typicality** refers to whether a child fits in with others of the same sex, likes to do the same kinds of things as others of the same sex, is good at the same kinds of things as others of the same sex, and in general displays the typical traits of being a girl or a boy. **Gender contentedness** means that a child likes being the sex proscribed at birth, does not think it would be more fun to be the opposite sex, and does not spend time wishing to do things that members of the

APPLYING THEORY AND RESEARCH TO LIFE

Children Raised by LGBT Parents

A growing number of LGBT couples are raising children. In many cases, the children were conceived in heterosexual marriages. Then one parent established a new relationship and continued to raise the child. Some couples have children conceived through artificial insemination, surrogacy, or other assisted reproductive technologies; other couples have assumed the parent role through adoption (Brodzinsky & Pertman, 2012; Richards, Pennings, & Appleby, 2012).

The emergence of this unique family structure provides an opportunity to better understand the process of gender-role socialization and the development of sexual orientation. Over 30 years of research has addressed the adjustment and development of children raised by LGBT parents. Many questions about child-rearing environments and child outcomes can be posed.

Do LGBT parents differ from heterosexual parents in their parenting strategies or parental-roles? When compared to heterosexual couples, lesbian couples exhibit more sensitive parenting and more egalitarian role relationships. Open disclosure of the lesbian relationship, the ability to maintain ties with the rest of the child's family, and a perception that the partners share equally in the tasks associated with household and child care all contribute to the child's emotional well-being (Patterson, 1995; Tasker, 2005).

How relevant is a parent's sexual orientation in shaping a child's gender-role identification and psychological well-being? In general, studies of the well-being, cognitive levels, and emotional adjustment of children growing up with LGBT parents find no differences between these children and those growing up in heterosexual families (Fitzgerald, 1999; Golombok, 2013; Lamb, 2012; Patterson, 2006). The children have gender-role preferences that are very similar to those of children growing up in heterosexual families (Patterson, 2009). Some studies of girls who are raised by lesbian mothers have observed that these young girls are more flexible in their play preferences (e.g. enjoying play with pretend firetrucks and carpenter's tools as well as with dolls and tea sets), and more likely to aspire to male-dominated occupations than girls raised by heterosexual mothers (Fulcher, Sutfin, & Patterson, 2008). No differences in gender identity or psychological well-being were observed.

One report reviewed findings from 23 studies of children of lesbian and gay parents (Anderssen, Amlie, & Ytteroy, 2002). Of these studies, most were conducted in North America, but four focused on European samples. Twenty studies reported on children of lesbian mothers; three on children of gay fathers. The results of these studies were discussed in terms of seven outcomes: emotional functioning, sexual preference, stigmatization, gender-role behavior, behavioral adjustment, gender identity, and cognitive functioning. Not all studies measured all of these variables, and even when studies focused on common outcomes, they used a variety of methods to measure the same variables. The studies of children of gay fathers focused only on sexual preferences and stigmatization.

Despite the variations in approaches to sampling, measurement, and design, the studies reported quite similar results. Children of lesbian mothers did not differ from other children with respect to emotional or behavioral problems, gender identity, gender-role behavior, or cognitive functioning. Children's sexual preference was not related to their parents' sexual orientation. There was some greater sensitivity to stigmatization among children of lesbian and gay parents, with children in some studies reporting being teased about being gay or lesbian. Also, children gave more thought to whom they would tell about their parents' sexual orientation. However, these experiences were not associated with higher rates of emotional or behavioral difficulties. The authors concluded that the research, with its many flaws, provides a picture of basic similarity between children reared in gay or lesbian families and those reared by heterosexual families.

Research on transgendered parents and their children is relatively new. A few studies report that the child's well-being is supported when the transition happens at a young age, when the parents preserve a positive relationship, when the transition takes place in a well-planned and open process, and when the child can preserve a close, positive relationship with both parents (Coolhart, 2014; White & Ettner, 2007). In legal cases where the transgendered parent's custody or visitation rights are questioned, parents are encouraged to focus on evidence supporting the position that there is nothing about being transgender that limits a person's ability to be a warm, responsive parent and to raise a healthy, well-adjusted child (Cooper, 2013; Hippensteele, 2011).

Three aspects of family life have been found to promote a child's well-being: (1) the quality of the child's relationship with parents and parental figures, with particular emphasis on sensitivity and warmth; (2) the quality of the relationship between the parents, especially the importance of harmonious as contrasted with hostile relationships; and (3) the availability of adequate economic, social, and physical resources (Lamb, 2012). These factors are predictive of well-being and positive adjustment across all types of family structures and family kinship relations. The sexual orientation of parents is not a significant predictor of a child's gender identification, future sexual orientation, or well-being (Herek, 2006). Given this conclusion, it makes sense to stop comparing LGBT families to heterosexual families and to begin exploring the unique characteristics of diverse families that contribute to their enactment of effective parenting, positive adult relationships, and their access to essential financial, social, and community resources.

With regard to LGBT families, children whose parents have formed a positive gender identity including acknowledgment and disclosure of their sexual orientation will be more comfortable talking about these topics with their children. Young children who perceive that their parents are guarded or threatened because of their sexual orientation may internalize this

Courtesy of Philip Newman

Parental warmth, sensitivity, and responsiveness; close, loving relationships between the partners; and adequate financial and social resources support a child's adjustment and well-being across all types of family structures.

sense of fear, even though they do not have a full understanding of its origin or how to cope with it (Telingator & Patterson, 2008). As the legal and societal environments have shifted to affirm marriage equality, more LGBT adults can live openly in their community, disclosing their identities without fear of threat or social isolation. The growing literature on parent–child relationships and kinship bonds in LGBT families is broadening and enriching our understanding of basic constructs such as family, parenting, mother and father, kinship, and gender (Golombok, 2015; Hicks, 2013).

Critical Thinking Questions

1. Based on what you have read about gender identification, describe the role you would expect a parent's sexual orientation to play in the way gender identification is formed.
2. Same-sex couples must take a highly planned, and sometimes very expensive, approach to having children. Hypothesize about how this might influence their approach to parenting.
3. If you were asked to design research to study the child-rearing practices and gender socialization of LGBT parents, what factors would you want to take into account? What would you measure? Who would be your comparison group? Why?
4. Describe the features of the community that might make it more comfortable or more difficult for gay and lesbian parents to disclose their sexual orientation and for their children to talk comfortably about the unique features of their families.

opposite sex can do. In their research, Egan and Perry found a strong and consistent relationship between gender typicality and measures of self-esteem, social competence, and acceptance from both male and female peers. The greater social pressure children felt to conform to gender-role norms, the more important gender contentedness was in sustaining self-esteem and perceived social competence. Those children who were not content about being a boy or a girl and also perceived a lot of pressure to conform to gender stereotypes experienced lower self-esteem.

Generally, there is more latitude or flexibility around the behaviors that are viewed as acceptable for young girls than for young boys. Little boys are more frequently stigmatized for acting in what is considered girlish ways and are more likely to experience peer rejection if their behaviors are deemed gender atypical. As a result, a nonconforming gender preference is more likely to be a source of distress for boys (Hegarty, 2009; Wallien, vanGoozen, & Cohen-Kettenis, 2007).

Both boys and girls can have experiences, like those described by Lee in the case study Gender Identification in Early Childhood, when their personal preferences for play behaviors, friends, and interests do not seem to fit with the cultural standards or stereotypes for their sex. In most cases, children and adults recognize these preferences as expressions of a child's unique temperament or personality. The term "tomboy" reflects this idea, as it refers to girls who prefer activities and clothes that are typically associated with boys. Girls who identify themselves as tomboys have been found to describe themselves as less like a typical girl, and less content about gender expectations for being a girl. At the same time, they had fewer biases about same-sex and other-sex behaviors and were more accepting of other children who engaged in behavior that violated gender-related norms (Ahlqvivst, Halim, Greulich, Lurye, & Ruble, 2013).

Gender preference can be influenced by environmental cues as to the value of one sex or the other. The cues may emanate from the family, ethnic and religious groups, the media, social institutions (such as the schools), and other culture carriers. Many cultures have traditionally valued men more than women and have given men higher status. For example, among Japanese immigrants who came to the United States between the 1890s and early 1900s, a strong value was the commitment to a hierarchical and male-head-of-household view of the family (Ishii-Kuntz, 1997):

> The Issei (*first-generation immigrant families*) customarily designated their eldest son the successor to the family business. . . . Accordingly, the eldest Nisei (*second-generation*) son usually received special treatment and

> privileges from his parents. In many Issei families, he was the second to be served at meals, after his father, and he was generally indulged by his mother. . . . Younger siblings were instructed to obey his directions, and even older sisters were expected to defer to him. (Ishii-Kuntz, 1997, p. 138)

To the extent that a cultural preference for males is communicated to children, boys are likely to establish a firmer preference for their sex group, and girls are likely to experience some ambivalence toward, if not rejection of, their sex group. Parental preference for one sex over the other can influence the quality of parent–child interactions and the resources, interactions, and opportunities available to boys and girls as they are growing up. The attainment of gender preference is a more complex and dynamic accomplishment than might be imagined. In fact, one's gender preference may fluctuate at different stages of life, particularly as one perceives gender-based changes in access to roles, resources, and social status (Maccoby, 2002).

In contrast to gender-nonconforming children who resist the constraints imposed on their gender, some children say they want to be the opposite sex. They may have a strong aversion to some or all of the physical characteristics and/or social and cultural expectations associated with the sex they were assigned at birth. The term **transgender** reflects this feeling of disconnect between one's gender preference and one's assigned sex. This conscious confusion about one's basic gender identity is undoubtedly a source of some distress. However, it appears that many transgender children are able to express their gender role preferences clearly (Olson, Key, & Eaton, 2015). When parents understand and affirm their child's reality, talk openly about it, and find ways to advocate for their child in the family and school contexts, they can reduce the child's feelings of isolation and minimize exposure to harassment and discrimination (Pyne, 2016). However, when children are subjected to parental and/or peer rejection, discrimination, and stigmatization around their nonconforming gender identity, they are more likely to experience symptoms associated with **gender dysphoria**, including intense distress, anxiety, and depression often accompanied by negative self-image and social withdrawal (APA Task Force on Gender Identity and Gender Variance, 2009; American Psychiatric Association, 2016).

We have reviewed four components of gender identification: (1) developing an understanding of gender, including learning and using gender labels, understanding gender stability and constancy, and understanding the genital basis of gender; (2) learning gender-role standards and stereotypes, and applying them to play activities, preferences for toys and clothes, and attributing them to others; (3) identifying with parents; and (4) establishing a gender preference, which may or may not coincide with one's assigned sex. What was once viewed as a predominantly biological process of sex role differentiation unfolding into a socially scripted gender role is now viewed as a product of each person's active integration of biological, cognitive, behavioral, and social factors.

A child's gender identity becomes a basic cognitive scheme that influences the interpretation of experiences (Leaper & Bigler, 2011). Children learn that people are grouped into two sexes—male and female. In our society, this dichotomy imposes itself on a wide array of social situations, including work, play, school, and politics—arenas where one's genital sex is not especially relevant. Once children learn this powerful category, they go about the business of figuring out how to apply it to themselves and others. They form expectations based on this categorization—that certain toys, interests, and behaviors are appropriate for boys and others are appropriate for girls; that certain activities, dispositions, and occupations are appropriate for men and others for women. These expectations are generally reinforced by the beliefs of the older children and adults with whom children interact. Some children do not conform to the gender norms and expectations associated with their assigned sex. They may resist these expectations or express a preference to reject their assigned sex altogether. The gender schemes that are conceived during childhood guide a child's daily activities and shape a preliminary vision of oneself in the future. Gender-based beliefs may become integrated into moral development, so that children begin to believe that it is morally right to adhere to certain gender-role standards and morally wrong to violate these standards.

FURTHER REFLECTION: *Consider the biological, psychological, and societal factors that contribute to whether a young child is viewed as "gender typical" or "gender atypical." What might be some consequences for subsequent development of being gender typical or gender atypical in early school age?*

Early Moral Development

OBJECTIVE 2 Summarize the process of early moral development, drawing from theories and research to explain how knowledge, emotion, and action combine to produce internalized morality.

The moral dilemmas facing young children are not about plagiarism or cloning or abortion. Rather, they are about understanding that lying, cheating, stealing, hurting others, or making fun of other children's differences are morally wrong and that telling the truth, playing fairly, sharing, being helpful, and respecting people's differences are morally right. The following analysis of moral development focuses on how children learn moral standards and apply them to their own behavior as well as the behavior of others. For early-school-age children, achievements in moral development include changes in three interrelated domains:

1. *Emotions.* (a) Experiencing the array of emotions that foster caring about others and that produce anxiety, guilt, and remorse when a moral standard has been violated; and (b) recognizing these emotions in others.
2. *Knowledge.* Learning the moral code of one's family and community and making judgments about whether something is good or bad, right or wrong.
3. *Action.* Taking appropriate actions to inhibit negative impulses, to act in accordance with rules and requests, to obey parents and other authorities, and to act in a caring, helpful manner, depending on the situation.

Internalization

Early moral development involves a process called **internalization**, which means behaving according to parental standards, rules, and values without external monitoring and constant reminders. This process, sometimes referred to as the formation of a conscience, requires that the child experience moral emotions, understand the family and community's moral code, and be able to take appropriate actions to either inhibit bad behavior or enact good behavior (Aksan & Kochanska, 2005).

Toddlers typically feel that demands for proper behavior do not come from within themselves, but from parents and other adults or older siblings. During early school age, standards and limits gradually become part of a child's self-concept. Specific values may be acquired primarily from parents, but they become integrated elements of the child's worldview.

Internalized morality includes both inhibiting harmful or socially unacceptable impulses and striving to do what is right. This is often characterized as the *want versus should conflict*. A child *wants* to indulge impulses for immediate expression or pleasure but knows that there *should* be a consideration for the consequences of those behaviors (Milkman, Rogers, & Bazerman, 2008). For example, a 5-year-old boy may take great delight in teasing his dog by threatening it with a stick. During one of these attacks, his mother scolds him. She insists that he stop and explains that it is cruel to hurt or frighten the dog. She may have to remind the boy on several other occasions that hitting the dog is not permitted. He may see the dog lying calmly in the sun and, with a gleam in his eye, begin to pick up a stick. He wants to hit the dog. At that moment, his behavior is interrupted by a feeling of tension, which is accompanied by the thought that he shouldn't hit the dog. If the standard has been successfully internalized, the emotional tension and the thought will be sufficient to inhibit the boy from hitting the dog. Internalization of the moral code is accompanied by increased control over one's behavior.

The following sections address various ways of understanding how the process of internalization unfolds in childhood. First, we review five theoretical perspectives that address aspects of moral development: learning theories, cognitive developmental theory, psychoanalytic and object relations theories, and evolutionary theory. Second, we review the related concepts of empathy, care, and perspective taking as they contribute to the internalization of morality. Third, we consider how a parent's discipline strategies may influence a child's morality. Finally, we consider media, including television and video games, as influences on moral development.

Five Theoretical Perspectives on Moral Development

The five theoretical approaches presented here—learning theories, cognitive developmental theory, psychoanalytic and object relations theories, and evolutionary theory—each offer distinct views about the way morality becomes internalized. You may find it helpful to refer back to chapter 2 (Major Theories for Understanding Human Development) to review the basic concepts of these theories.

These theories focus on the *process* of moral development, not the content. Each culture or subcultural group has its own set of moral standards. For example, in many Asian cultures, children are taught that teachers should be highly revered. Children learn to show respect to a teacher and to view their teachers as important role models. Children who are disrespectful of a teacher would be shamed. In the United States, the role of teacher does not have high status in comparison to many other occupations. Parents may express criticism of teachers openly in front of their children. They may write excuses for children's absences or failure to complete their homework, even though both the children and parents know these excuses are fabrications. Children may learn that some teachers are fair and helpful, but others are not. They may not consider it immoral to ignore a teacher's request or to make fun of a teacher with the other children. The theories that follow suggest how children internalize moral standards; they do not explain what the standards are or suggest what they should be.

Learning Theories. The focus of learning theories is on the conditions that support moral behaviors or actions. Moral behavior and the process of internalization are viewed as responses to environmental reinforcements and punishments. Moral behaviors can be shaped by the *consequences* that follow them. A positive, prosocial behavior, like helping to put the toys away or comforting another child who is distressed, is likely to be repeated if it is reinforced. In contrast, if a behavior is ignored or punished, it is less likely to occur again. If a child performs a misdeed or defies an authority and suffers negative consequences, these consequences ought to reduce the likelihood that such behavior will recur. If a child is in an unpleasant or painful environment and performs a behavior that reduces or eliminates the unpleasantness, the child is more likely to perform this same behavior again in similar situations. For example, if a child says, "I'm sorry. I'll try to do better next time," and this apology reduces the parent's anger or irritability, this behavior is likely to be repeated at other times when the parent is angry at the child. According to learning theory, internalization results as the behaviors that lead to a more comfortable, less threatening environment become more common and the behaviors that produce parental anger or conflict disappear.

The special case of **avoidance conditioning** is a paradigm for understanding how internalization is sustained. Having been disciplined in the past for wrong-doings, a child contemplating a misdeed should feel tension. Avoiding or inhibiting the impulse to misbehave reduces the tension and is therefore reinforcing. This process may occur even when the person who was involved in administering the discipline is absent. In other words, the scenario of thinking about a wrong or naughty action, feeling the anxiety that is associated with past discipline, and reducing that anxiety by exercising restraint may take place mentally, without any observable behavior. Over time, the reinforcement of tension reduction that is linked to controlling a wrongful impulse strengthens the tendency to inhibit it, and the child's behavior becomes less impulsive.

Social learning theory adds another mechanism for moral learning: the **observation of models**. By observing and imitating helpful models, children can learn prosocial behavior. When a child observes someone else perform a kind, generous, or selfless

My Chores
1. Clean my room.
2. Take out the trash.
3. Set the table.
4. Do my homew
5. Feed the dog.
6. Help with laundry

According to learning theory, Martin's willingness to do his chores and help around the house is strengthened because he receives a reward for his efforts. According to this theory, what would happen if Martin's father stopped giving him the reward?

act, it produces an uplifting emotional response. If the opportunity for positive or altruistic actions occurs, the child who has observed someone else's generosity is likely to be more caring or helpful as a result of having observed this positive action by others (Schnall, Roper, & Fessler, 2010).

By observing the negative consequences that follow the misdeeds of models, they can also learn to inhibit their own misbehavior. Their moral behavior is not limited to the actions they have performed—it may be based on expectations formulated from observations of how the conduct of relevant models has been rewarded or punished (Bandura, 1991). For example, early-school-age children are more likely to judge an act of televised violence as *right* if the act goes unpunished. If a police officer in a television episode hits a suspect and threatens them in order to get a confession, the police officer is typically not punished in the program. Having viewed such unpunished acts, children formulate abstract rules, concepts, and sets of propositions about when aggressive behavior is justified (Kremar & Cooke, 2001). According to this theoretical perspective, the specific situation will influence the extent to which moral behavior is displayed. Moral behavior is built on the accumulation of many experiences across different situations day after day where children learn which behaviors are acceptable and which are not.

Cognitive Developmental Theory.

In comparison to the learning theories, cognitive developmental theorists focus more on **moral reasoning** than on moral behavior. They emphasize a child's active construction of moral meaning, focusing on developmental changes in the ways children make judgments and reason about morally relevant situations. Piaget (1932/1948) described the major transition in moral judgment as a shift from heteronomous to autonomous morality. In **heteronomous morality**, rules are understood as fixed, unchangeable aspects of social reality. Children's moral judgments reflect a sense of subordination to authority figures. An act is judged as right or wrong depending on the letter of the law, the amount of damage that was done, and whether or not the act was punished.

In **autonomous morality**, children see rules as products of cooperative agreements. Moral judgments reflect a child's participation in a variety of social roles and in egalitarian relationships with friends. Give-and-take with peers highlights mutual respect and mutual benefit as rewards for holding to the terms of agreement or abiding by the law. Piaget posed situations like the following to young children in order to help clarify the difference between heteronomous and autonomous morality.

> Mark rushes into the kitchen, pushing open the door. Although he did not realize it, his mother had left a set of 10 cups and saucers on a stool behind the door. When he pushed the door open, the cups and saucers fell off the stool and broke.
>
> Matt was climbing up on the kitchen counter to reach some cookies that his mother told him he was not supposed to eat. While climbing on the counter, he broke 1 cup and saucer.
>
> Who committed the more serious moral transgression? Which boy should be more severely punished?

Children operating with a heteronomous morality believe that the child who breaks 10 cups by accident has committed a much more serious transgression than the child who broke only 1. Children who have achieved an autonomous morality believe that the child who disobeyed and violated his mother's trust committed the more serious transgression. In general, younger children are likely to judge the moral seriousness of an action based on the magnitude and nature of the consequences. If an action, no matter what the intent, produced harm, it should be punished. Older children are able to consider both the intention and the consequences in making a moral judgment. If an action was intended to harm and produced harm, it should definitely be punished (Helwig, Zelazo, & Wilson, 2001).

Expanding on the distinction between heteronomous and autonomous morality, cognitive developmental theorists have described a sequence of stages of moral thought (Kohlberg, 1976; Smetana, Jambone, & Ball, 2013). As children become increasingly skillful in evaluating the abstract, logical components of a moral dilemma, their moral judgments change. At the core of this change is the mechanism called **equilibration**—efforts to reconcile new perspectives and ideas about basic moral concepts, such as justice, intentionality, and social responsibility, with existing views about what is right and wrong. Children's reasoning may be thrown into disequilibrium by external sources, such as their parents' use of explanations and inductions regarding a moral dilemma or encounters with friends who reason differently about a moral conflict. Children's own cognitive maturation, especially the ability to think abstractly and hypothetically about interrelated variables, determines how their reasoning about moral dilemmas will be structured (Piaget, 1978/1985; Walker, Gustafson, & Hennig, 2001).

As summarized in Table 7.1, Kohlberg (1969, 1976) described three levels of moral thought, each characterized by two stages of moral judgment. Each level reflects a more cognitively abstract approach to matters of justice, fairness, and social responsibility. At Level I, **preconventional morality**, Stage 1 judgments of justice are based on whether a behavior is rewarded or punished. Stage 2 judgments are based on an instrumental view of whether the consequences will be good for "me and my family." The first and, to some degree, the second stage of Level I characterize children of early school age. Level II, **conventional morality**, is concerned with maintaining the approval of authorities at Stage 3 and with upholding the social order at Stage 4. Level III, **postconventional morality,** brings an acceptance of moral principles that are viewed as part of a person's own ideology rather than simply being imposed by the social order. At Stage 5, justice and morality are determined by a democratically derived social contract. At Stage 6, a person develops a sense of universal ethical principles that apply across history and cultural contexts.

Table 7.1 Stages in the Development of Moral Judgment

LEVEL I: PRECONVENTIONAL
Stage 1 Judgments are based on whether behavior is rewarded or punished.
Stage 2 Judgments are based on whether the consequences result in benefits for self or loved ones.
LEVEL II: CONVENTIONAL
Stage 3 Judgments are based on whether authorities approve or disapprove.
Stage 4 Judgments are based on whether the behavior upholds or violates the laws of society.
LEVEL III: POSTCONVENTIONAL
Stage 5 Judgments are based on preserving social contracts based on cooperative collaboration.
Stage 6 Judgments are based on ethical principles that apply across time and cultures.

According to this theory, the stages form a logical hierarchy. At each new stage, individuals reorganize their view of morality, realizing the inadequacy of the preceding stage. For example, once a person sees morality in terms of a system that upholds and protects the social order (Stage 4), then the reasoning that argues for an act as moral because it was rewarded or immoral because it was punished is seen as inadequate. The stages form an invariant sequence, moving from a very idiosyncratic, personal view of morality to a view in which rules and laws are obeyed because they have been established by an authority or a society, and finally to an understanding of rules and laws as created to uphold basic principles of fairness, justice, and humanity (Boom, Brugman, & van der Heijden, 2001).

Consistent with this theory of moral development, early-school-age children can be expected to reason about moral situations at Level I, preconventional morality, which is dominated by concerns about the consequences of their behavior. This is quite consistent with the learning theory view that morality is shaped by the consequences that follow behavior in specific situations. However, children understand that not all misbehavior involves a moral transgression. Some behaviors violate social norms or expectations, sometimes called social transgressions, that are situation specific: "Don't talk with your mouth full," "Take your empty plate to the kitchen," or "Say 'Thank You' to the waitress when she brings you your food." Young children understand the difference between moral transgressions like lying, hitting, or taking something that doesn't belong to you, and social transgressions, which are violations of social convention (Smetana, Schlagman, & Adams, 1993; Turiel, 2002).

Moreover, a child's moral reasoning can be altered by exposure to an environment that encourages children to participate actively in creating the moral climate. For example, in the preschool and early primary grades, children can function at a more flexible, autonomous level when the moral atmosphere

Hannah got in trouble in school today for talking back to her teacher. Now her mother is trying to explain that it is wrong to be disrespectful to teachers. At the preconventional level of morality, Hannah just thinks it's wrong if you get punished. Lots of other kids are disrespectful to the teacher and nothing ever happens to them.

consistently emphasizes mutual respect. Classrooms where children are involved in rule making and conflict resolution give children an opportunity to appreciate each other's perspectives and to construct a social order that is largely regulated by the children themselves (DeVries, Hildebrandt, & Zan, 2000).

The notion that people move through a hierarchical sequence of stages of moral reasoning prompted by a process of cognitive disequilibrium has been challenged on a number of fronts. The direction of development over the stages has been viewed as too linear, valuing justice over social cooperation. It has been criticized as embodying a Western cultural orientation and a male-oriented value system that places the individual good and individual freedoms above the good of the group or community (Arnold, 2000). For example, in the African Ubuntu/Botho community, "actions are right roughly insofar as they are a matter of living harmoniously with others or honoring communal relations" (Metz & Gaie, 2010). However, cross-cultural comparisons have found support for the idea that as people mature, they find increasingly sophisticated ways of approaching moral situations. A study of more than 500 high school and university students in Taiwan found that the students showed evidence of high levels of postconventional reasoning, even though they adopted a culturally collectivist Chinese moral ethic (Gielen & Miao, 2000). Longitudinal studies in a variety of countries have observed an evolution of moral thought much like that proposed by Kohlberg, in which the reasoning shifts from an idiosyncratic to a more principled approach to evaluating moral conflicts (Gielen & Markoulis, 2001).

Psychoanalytic and Object Relations Theories. The psychoanalytic theorists focus on the ability of children to control their impulses and resist temptation, rather than on their cognitive reasoning about what constitutes a moral transgression. This theoretical perspective addresses moral emotions, especially guilt about having harmful or naughty impulses and pride in behaving in accord with one's ideals, as they contribute to moral behavior. According to psychoanalytic theory, a moral sense develops as a result of strong parental identification. Classical psychoanalytic theory views a child's conscience, or **superego,** as an internalization of parental values and moral standards. It holds that the superego is formed during the phallic stage, between the ages of about 4 and 7, as a result of the conflict between a child's sexual and aggressive impulses and the ways in which the parents deal with the behavioral manifestations of those impulses.

Freud (1925/1961) suggested that the more severely a parent forced a child to inhibit impulses, the stronger the child's superego would be. Research on the development of conscience has failed to support Freud's hypothesis. The children of parents who use harsh physical punishment do not have higher levels of internalization. These children are likely to inhibit impulsive behaviors in the presence of their parents, but when they are observed with their peers away from home, they tend to be physically aggressive and do not control their behavior well. Parental warmth, limited use of power assertion, involving children in decision making, and modeling resistance to temptation contribute to high levels of prosocial behavior and social responsibility.

In contrast to Freud's views on the formation of conscience, **object relations theory** views the critical time for moral development as infancy rather than the early-school-age years (Klein, 1932/1975; Kohut, 1971; Mahler, 1963; Winnicut, 1958). Infants develop an awareness of three domains: the body and its physical experiences and needs, the existence of others, and the relations between the self and others (Sharp, Fonagy, & Goodyer, 2008). All subsequent psychological growth must be assimilated into these three domains. According to this view, the origins of moral reasoning and behavior have links to early feelings about the self and its needs, especially feelings of pleasure and pain, and the way these feelings are mirrored or accepted by the loving caregiver.

Blend Images - KidStock/Getty Images

According to the psychoanalytic view, young children act on their impulses. As the superego develops, they are more successful at resisting temptation.

Morality has a basis in a young child's awareness of valued others and in behaviors that strengthen or threaten the bonds between the self and these others. All humans are seen as confronted by a dynamic tension between positive and negative emotions—love and hate, kindness and cruelty. One basis of early morality lies in the child's own sense of self-love, a wish to enhance and not harm or violate the self. Another basis is the extension of this self-love to the other and the wish to preserve feelings of connection, trust, and security that have been established in the early parent–infant relationship.

Through experiences with sensitive caregiving, infants become increasingly aware of the loved object as an integrated whole with feelings, motives, and goals as well as a physical reality. At the same time, this realization about the other fosters the child's own awareness of his or her inner mental life. When a child is distressed, for example, a calm, reassuring caregiver will use a certain tone of voice, facial expressions, and comforting strategies to help the child cope with the difficulty. This gives the child a chance to feel safe about experiencing the inner world of painful emotions. The loving caregiver allows the child an intimate context in which to encounter these impulses, emotions, and fears. As a result, the child does not have to split off from his or her angry, vengeful self or project it onto others. By seeing the loved other as both good and bad, and the self as both good and bad, the child's capacity for caring and empathy expands (Fonagy, Gergely, & Target, 2010; Fonagy, Luyten, Allison, & Campbell, 2016).

Longitudinal studies have provided support for the link between experiences of mutually responsive care in infancy and later moral emotion and behaviors (Kochanska, Forman, Aksan, & Dunbar, 2005). Children whose relationship with their mothers was characterized as mutually responsive in infancy showed stronger moral emotions, including greater distress over another person's pain and distress, and greater remorse after having damaged a valued toy. These children also showed greater restraint in resisting temptation and higher levels of compliance with requests from a parent or an experimenter when they were left alone. The early experiences of mutuality with a caregiver are transformed over time into enjoyment during child–caregiver interactions, greater willingness for compliance, and less need for the use of power assertion or monitoring to ensure compliance.

Evolutionary Theory. The evolutionary perspective emphasizes an emotional as well as a cognitive aspect to morality. Haidt (2007, 2008) characterized these components as **moral intuition** and moral reasoning. The emotional or intuitive component is a more primitive, immediate, almost automatic system that evaluates experiences as positive or negative, good or bad, without going through steps of searching for more information or weighing evidence. The moral reasoning component is thought to have evolved later, along with language, and is used to reach a moral judgment or decision. According to the evolutionary view, the moral reasoning component is slower than moral intuition and is often used to justify the initial moral intuition.

Certain areas of the brain, especially the amygdala and insula, produce emotional alarms, signaling fear or danger, as well as positive responses to stimuli. Social emotions, including lust and disgust, pride, humiliation, and guilt, which are processed in the insula, contribute to moral intuition. These affective areas operate to produce an orienting emotion that colors subsequent judgments. When people are told a moral story or dilemma, they typically have an immediate emotional reaction. They then begin to use reason to justify this reaction. Sometimes, they can override the initial intuitive reaction, most commonly when they interact with others who might stimulate a different, alternative emotional reaction to the situation.

According to an evolutionary view, morality, especially altruism and care for others, and fairness and reciprocity in social interactions, helps to sustain families and bind members of groups together. If you think about human evolution, you can appreciate that human infants have a relatively long period of dependence; and human infants can be born relatively close together. So it is likely that in early human families, parents had to care for several infants and young children at the same time. In order for a family to survive, slightly older children, even as young as 3, would need to contribute to the functional requirements of the family, such as carrying water, collecting firewood, or watching an infant sibling. As a result, helping behavior can be viewed as contributing to an adaptive advantage that has carried forward to contemporary human children. The motivation to help and the skills associated with helping behaviors can be observed very early in childhood across many cultures (Warneken, 2015).

Early human groups that were able to create a moral code that rewarded and increased behaviors beneficial to the group and that punished or reduced selfishness would have been more successful in attracting new members and fighting off competing groups. Thus, morality is thought to have co-evolved with the formation of larger human communities in which individuals are tied together beyond the basis of immediate kinship. As part of this process, rites, rituals, and institutions have emerged that link emotions, motor behaviors, and states of consciousness of large groups of people such that they are more attuned to one another than to members of out-groups and more willing to share resources, behave in a caring way, and exhibit loyalty to others in their group (Hauser, 2006).

Whereas the cognitive developmental and psychoanalytic perspectives focus on individuals and how they manage to control their antisocial impulses, the evolutionary emphasis is on the benefit of moral emotions for the protection and preservation of the group. Five components have been found to be incorporated in the moral codes of many cultures: (1) a belief that one should protect one's kin and members of one's group from harm and provide care for them; (2) a belief that one should behave fairly and exercise reciprocity (an equal give and take) with members of one's group; (3) a belief that one should be loyal to members of one's group; (4) a belief in respect and obedience to authority; and (5) a belief that one should follow practices that preserve bodily and spiritual purity, living in sacred or sanctioned, not a disgraceful or disgusting, way (Graham et al., 2011; Haidt, 2007, p. 1001). These content areas are elaborated to varying degrees by each cultural group, given more or less prominence in various religious teachings, and passed along from generation to generation through parental socialization, stories, and rituals. All five of these moral domains operate to build and strengthen communal bonds, creating a framework for how people should treat others, how they expect others to treat them, and how they should function in a larger social group.

— **CASE STUDY** Early Learning About Obedience —

Jung Chang describes the moral environment to which she was exposed in her early childhood years through interactions with her grandmother.

For my grandmother, all flowers and trees, the clouds and the rain were living beings with a heart and tears and a moral sense. We would be safe if we followed the old Chinese rule for children, *ting-hua* ("heeding the words," being obedient). Otherwise all sorts of things would happen to us. When we ate oranges my grandmother would warn us against swallowing the seeds. "If you don't listen to me, one day you won't be able to get into the house. Every little seed is a baby orange tree, and he wants to grow up, just like you. He'll grow quietly inside your tummy, up and up, and then one day, Ai-ya! There he is, out from the top of your head! He'll grow leaves, and bear more oranges, and he'll become taller than our door. . . ."

The thought of carrying an orange tree on my head fascinated me so much that one day I deliberately swallowed a seed—one, no more. I did not want an orchard on my head; that would be too heavy. For the whole day, I anxiously felt my skull every other minute to see whether it was still in one piece. Several times I almost asked my grandmother whether I would be allowed to eat the oranges on my head, but I checked myself so that she would not know I had been disobedient. I decided to pretend it was an accident when she saw the tree. I slept very badly that night. I felt something was pushing up against my skull. (Chang, 1991, pp. 208–209)

CASE ANALYSIS Using What You Know

1. Describe the moral lesson of this case.
2. Explain how the case illustrates the themes of moral emotion, knowledge, and action.
3. Discuss how this case illustrates the particular orientation of early-school-age children to moral dilemmas.
4. Analyze this case as it relates to the psychosocial crisis of initiative versus guilt.

The study of moral development has been expanded through research in several directions. The research on empathy and perspective taking focuses on how children come to know and understand others. These abilities are essential for moral action. The research on parental discipline highlights the socialization process that supports self-regulation and internalization of moral values, including the passing on of a moral code from one generation to the next. The research on media, including television and video games, illustrates the co-evolution of morality and culture.

Empathy, Caring, and Perspective Taking

Empathy, caring, and perspective taking are factors that contribute to a child's ability to care about another person's distress, to consider the other person's needs and intentions when judging a moral act, and to respond in a helpful way.

Empathy. **Empathy** has been defined as the ability to understand and feel the perceived emotions of another person, for example feeling sad when someone else is sad. This definition emphasizes one's emotional reaction to the observation of another person's emotional condition. By merely observing the facial expressions, body attitudes, and vocalizations of another person, a child can identify that person's emotion and feel it personally. The range of emotions with which one can empathize depends on the clarity of the cues the other person sends and on one's own prior experiences. Research on the mirror neuron system discussed in chapter 6 suggests that humans are neurologically and psychologically prepared to synchronize their feelings and movements with others, thus enhancing the capacity for empathy. The capacity for empathy is deeply embedded in our evolutionary history, suggesting adaptive advantages for groups where the capacity for empathy is genetically passed along from one generation to the next (Dalai Lama & Ekman, 2008).

The capacity for empathy begins in infancy. Infant imitation, observed in the first months of life, provides an initial link between the observation of emotional expressions in another person and the expression of that emotion (Meltzoff, 2010). Infants appear to be able to recognize and interpret auditory and facial cues that suggest emotional expressions in others. In the newborn nursery, when one infant starts to wail, the other infants begin to cry. Following from object relations theory, the intimate infant–caregiver relationship forms an early framework for empathy. The coordination of rhythmic interactions, the creation of joint attention, and the achievement of intersubjectivity through early gestures and words provide infants with an understanding of their caregiver's state. In a study of 125 firstborn girls, empathic concern for their mothers' distress was observed to increase from 16 months to 22 months of age. In contrast, empathic concern for a stranger was observed to decrease. In infancy, empathy for others appears to be situational, requiring an ability to overcome wariness or fearfulness in order to offer comfort to another person (van der Mark, van IJzendoorn, & Bakermans-Kranenburg, 2002).

Early-school-age children can usually identify the circumstances that may have produced another child's emotional response, especially anger and distress, and they can understand and empathize with another child's feelings. Children are most likely to think that external events produce emotional reactions: "The teacher made her put her toys away," or "He tripped over the blocks." But they can also think about internal states that may produce strong emotions: "He's mad because he didn't get a turn," or "She's sad because her stomach hurts." The ability to understand the emotions and mental state of another person allows children to justify someone's moral behavior and perhaps to forgive a transgression: "The dad just spilled juice on his paper, so he yelled at his daughter. He was upset; he didn't really mean it." The ability to identify pleasurable and unpleasurable emotions in others and to empathize with them makes the child receptive to moral teachings.

Caring. It is one thing to feel empathy for someone else, and yet another to take action to help that person. The **principle of care** refers to a sense of duty or obligation to help someone who is in need. Caring may build upon the emotions aroused by empathy. However, the principle of care also requires a cognitive evaluation of the other person's situation and an action component—the desire or intention to do something to help. From a developmental perspective, the principle of care reflects a greater degree of cognitive awareness than empathic distress and an internalized moral standard that one should do what one can to reduce another

pavla/Shutterstock.com

Young children can be very caring and supportive in comforting others, especially if they understand the reason behind another child's distress.

person's distress (Eisenberg, Fabes, & Spinard, 2006; Wilhelm & Bekkers, 2010). Even at very young ages, as young as 18 months or 2 years, many infants are able to help others and seem to want to do this. They can pick up an object that someone else has dropped, or reach under a chair or table to retrieve something that is out of reach. The capacity and motivation for helping both adults and peers matures rapidly between the ages of 2 and 5 (Hepach, Vaish, & Tomasello, 2012).

Although most children who experience empathy are also inclined toward caring actions, some children are characterized by callousness and disregard for others. Not surprisingly, these characteristics in early childhood have been found to predict antisocial behavior in middle childhood and adolescence. The origins for this deficit in caring are not fully understood. Twin studies suggest possible genetic origins, and studies of harsh parenting implicate environmental influences (Rhee et al., 2013; Waller et al., 2012).

Perspective Taking. The terms *empathy* and *perspective taking* are sometimes confused. Empathy typically refers to the ability to identify and experience the *emotional* state of another person. **Perspective taking** refers to the *cognitive* capacity to consider a situation from the point of view of another person. This requires a recognition that someone else's point of view may differ from one's own. It also requires the ability to analyze the factors that may account for these differences (Flavell, 1974; Piaget, 1932/1948). Perspective taking is closely linked to a child's theory of mind. It requires a child to consider what another person might know or feel, especially when that person's experiences differ from the child's own point of view.

Imagine a child who wants to play with another child's toy. If the first child thinks, "If I had that toy, I would be happy, and if I am happy, everyone is happy," then that child may take the toy without anticipating that the other child will be upset. This is evidence of a lack of perspective taking. Whereas empathy provides an emotional bridge that enables children to discover the similarities between self and others, it does not teach them about differences. Recognizing these differences requires perspective taking. The capacity to take another person's perspective is achieved gradually through parental inductions, peer interaction, social pretend play, conflict, and role-playing.

Children at ages 4 and 5 frequently exhibit prosocial behaviors that evidence an understanding of others' needs. The most common of these behaviors are sharing, cooperating, and helping. Two examples illustrate the nature of this kind of social perspective taking:

> The path of a child with an armload of play dough was blocked by two chairs. Another child stopped her ongoing activity and moved the chair before the approaching child reached it.
>
> A boy saw another child spill a puzzle on the floor and assisted him in picking it up. (Iannotti, 1985, p. 53)

Many moral dilemmas require that children subordinate their personal needs for someone else's sake. To resolve such situations, children must be able to separate their personal wants from the other person's. One longitudinal study followed children from the ages of 4 and 5 into early adulthood. Those children who showed spontaneous sharing, helping, and other prosocial behaviors in the early childhood years continued to exhibit prosocial behavior, sympathy, and perspective taking over the course of adolescence and early adulthood (Eisenberg et al., 1999). A combination of a genetically based social orientation, an ability to regulate or inhibit one's impulses, and a consistent socialization environment contribute to a young child's sympathetic response toward others' distress. Over time, this outlook combines with a more mature capacity for moral reasoning and deepening social ties that help sustain a prosocial orientation.

Although the capacity for perspective taking appears to be universal, some cultures rely on it more than others. For example, East Asian cultures, which tend to have a more collectivist orientation, emphasize the value of interdependence. As a result, from early childhood, East Asian children are encouraged to observe others carefully to determine signs of intentions and distress. In an experimental study, Chinese and American participants were paired up in a communication game. Chinese players were much more tuned in to their partners' nonverbal communications and intentions than were the American players, suggesting a cultural socialization that fosters perspective taking (Wu & Keysar, 2007).

Parental Discipline

Parents are a child's first teachers about the content of the moral code the child will be expected to internalize. Through their approach to discipline, parents make a stand for certain values, beliefs, and behaviors that embody their ideas about a moral way of life. When disciplining a child, parents emphasize that certain behaviors are wrong and should be inhibited; other behaviors are right and should be repeated. This distinction between good and bad behaviors and the accompanying parental approval or disapproval forms the content of a child's moral code. Ideally, the socialization process as well as the specific moral teaching should support a child's belief in a caring, just, and fair community. Discipline strategies that are unduly harsh or erratic are likely to undermine these values and produce a set of moral beliefs focusing on power, domination, and self-interest (Arsenio & Gold, 2006). What is more, as discussed in chapter 6, harsh discipline undermines a child's capacity for self-regulation, making it more difficult to exercise inhibitory control.

Parents use specific discipline techniques to bring about compliance with the moral code. Four elements are important in determining the impact of these techniques on a child's future behavior. The discipline should

1. Help the child interrupt or inhibit the forbidden action.
2. Point out a more acceptable form of behavior so that the child will know what is right in a future instance.
3. Provide some reasons, understandable to the child, why one action is inappropriate and the other more desirable.
4. Stimulate the child's ability to empathize with the victim of the misdeed. In other words, children are asked to put themselves in their victim's place in order to see how much they dislike the feelings they caused in the other person.

In considering discipline as a mechanism for teaching morality, one becomes aware of the many interacting and interrelated components of a moral act. The discipline techniques that are most effective in teaching morality to children are those that help children control their own behavior, understand the meaning of their behavior for others, and expand their feelings of empathy. Discipline techniques that do not include these characteristics, such as power assertion, may succeed in inhibiting undesired behavior but may fail to achieve the long-term goal of incorporating moral values into future behavior.

The child's temperament is often overlooked in determining the likely effectiveness of certain disciplinary techniques. For example, children who are especially fussy and irritable as infants are more likely to be spanked by their parents (Berlin et al., 2009). Children who are temperamentally fearful and inhibited in response to novel stimuli and who choose to stay close to their mothers during toddlerhood are especially sensitive to messages of disapproval. For these children, a small dose of parental criticism is adequate to promote moral internalization, and too much power assertion appears to be counterproductive. In contrast, children who are highly active and who are insensitive to messages of disapproval require more focused and directive discipline, especially a consistent program of recognizing and rewarding good behaviors and minimizing the situations and stimuli that may provoke impulsive or aggressive actions (Kim & Kochanska, 2012). In the face of anger-arousing events or distressing situations, some children are better able to regulate their emotions and return to a calm state than others. Children who are able to exercise emotional control and manage the physical conditions associated with mild distress are also more likely to be able to show prosocial behavior by expressing concern and trying to comfort others who are distressed (Scrimgeour, Davis, & Buss, 2016).

In addition to their use of discipline, parents guide moral development by modeling positive, prosocial behaviors and by talking with their children about moral issues. In chapter 6, we discussed the use of scaffolding to promote more effective communicative competence. In the same way, parents can scaffold their child's moral reasoning by talking with their children, raising questions about moral decisions their children are facing, and introducing new arguments or alternative views as their children think about moral conflicts. Security in the child–caregiver attachment, the expression of warmth and affection in the relationship, and a parent's willingness to talk about feelings and moral concerns all contribute to a child's early moral development (Dunn, 2006; Laible & Thompson, 2000).

For example, Beth's mother asks her to help pick up the toys and put them away. Beth says that her brother made the mess, and he should pick up the toys. Beth's mother might acknowledge Beth's frustration about picking up after her little brother, but then she could point out that Beth would be helping her by picking up the toys, and that at some time in the future, she will want her brother to help clean up a mess that Beth made. Meanwhile, it is important to pick up the toys so they do not get broken and so no one trips or falls over them. The idea that helping in a family is not just about what each person does, but about what is good for the family as a whole, challenges Beth's moral reasoning and encourages her to move to a new level of moral reasoning.

Parents encounter many examples when their children behave well and show signs of kindness, caring, and truthfulness. They also encounter times when their children misbehave, exhibiting selfishness, anger, or cruelty. Especially at times when children are experiencing emotional distress, parents teach and model positive moral behavior through their tone of voice, their willingness to hear a child's explanations, their willingness to provide explanations for their rules, and their ability to maintain open communication, even during conflict. Depending on the situation, parents may try to sooth the child with physical comfort, encourage the child to talk about his or her feelings, try to distract a distressed child, or try to reframe the situation to change the way the child is thinking or feeling about the problem. All these strategies can help children manage their distress and regain emotional control (Scrimgeour, Davis, & Buss, 2016). They convey a sense that we are all imperfect, that we continue to strive toward a moral ideal, and that we can forgive and try again.

The Impact of Media, Including Television and Video Games, on Moral Development

Moral influences extend beyond the family to include schools, religious institutions, and the community. Among the societal influences that have been a focus of research and policy is the impact of the media, especially television, video games, and Internet play, on children's attitudes and behaviors. Some people suggest that we need to think about the television as a part of the family system. In about 80 percent of homes, the television is on even when no one is watching. Family interactions are different in the presence of the television, involving less talking and

Zoom Team/ShutterStock.com

Steven is completely engrossed in his video game. Even though he is an active child, he can sit like this for long stretches. His mother has to set the timer to limit his play.

more touching. Images, information, and dramatic situations portrayed on television influence family members, resulting in new kinds of behaviors, shared experiences, points of discussion, and exposure to distressing images that may require comforting or interpretation (Gentile & Walsh, 2002). In families with siblings, it is not uncommon for younger children to "watch up" to the television interests of the older sibling. As a result, younger children may be exposed to programs when they are less able to understand them.

Violent Programming. What is the impact of exposure to *media violence* on the beliefs and behaviors of young children (Huesmann & Skoric, 2003)? Concern about media violence is particularly meaningful in the context of the child's growing moral consciousness. More than 30 years of laboratory experiments, field experiments, and analyses of naturally occurring behaviors have led to the conclusion that televised and video game violence has definite negative consequences for young children's behaviors and beliefs. Nonetheless, in 2011 the U.S. Supreme Court ruled that video games are protected as free speech and that the sale of these games to minors cannot be regulated or curtailed (Ferguson, 2013). As a result, the responsibility for establishing viewing practices rests entirely with families.

Those who monitor contemporary television viewing estimate that in the United States, children ages 2 to 5 watch an average of 32 hours of video and other recorded screen media each week (Nielsen, 2009). In comparison to older children, young children also tend to watch their favorite programs over and over again using alternative recording devices. An analysis of music television videos found that almost one fourth of the videos included images of violence and carrying weapons. Video games are especially permeated with violent themes. Many video games require children to become increasingly adept at killing off characters with the use of special weapons or superpowers. Studies suggest that long-term exposure to violent video game play is associated with lower empathy for others, increased aggressive behavior, and desensitization to real-life violence (Carnagey & Anderson, 2004; Funk, Baldacci, Pasold, & Baumgardner, 2004; Swing & Anderson, 2007).

The American Academy of Pediatrics issued a policy statement on television viewing in which they make the following recommendations (American Academy of Pediatrics, 2013):

1. Discourage television viewing for all children under age 2.
2. Remove televisions and Internet connected devices from children's bedrooms.
3. Limit children's total entertainment media time (television, video games, Internet play) to no more than 1 to 2 hours per day.
4. Monitor the media and programs that children are viewing, including websites and social media; focus on programs and games that are informational, educational, and nonviolent.
5. View TV, movies, and other media programs along with children and discuss the content.
6. Since children's viewing is often influenced by parents' viewing habits, establish family guidelines and limits for media use at home, such as a time away from media during mealtime or a nighttime close-off time for cell phones and devices.

These recommendations are based on research suggesting that about two thirds of current television programming contains a great amount of violence, and portrayals of violence are often glamorized and go unpunished. As a result, watching television and playing video games that have violent content have a strong impact on a child's willingness to engage in real-life violence, or they may be frightened by these violent images (Federman, 1998; Wilson et al., 2002). What is more, children's viewing patterns are associated with the amount of time parents watch television or other media and their choice of media content (Bleakley, Jordan, & Hennessy, 2013). This supports the notion that media violence can become an integrated aspect of the family system, influencing a young child's beliefs and values about aggressive behaviors.

At least three processes are at work that may increase the level of aggressiveness in children who are exposed to media violence (Bushman, Huesmann, & Whitaker, 2009) (see Table 7.2). First, children observe role models who perform aggressive actions. Especially when the hero is provoked and retaliates with aggression that goes unpunished, the child is likely to imitate the aggressive actions. Thus, viewing media violence adds new violent behaviors to the child's repertoire. Moreover, when the hero

Table 7.2 Three Processes That May Increase the Level of Aggression in Children Who Watch Media Violence

Process	Possible Consequence
Observing role models who engage in aggressive actions.	Imitation of violent action is likely when hero is provoked and retaliates with aggression. Hero is rewarded for violent actions. New violent behaviors added to repertoire.
Viewing aggressive actions leads to heightened level of arousal.	Brings network of aggressive thoughts, feelings, memories, and action tendencies into consciousness. Repeated stimulation strengthens this network. Stimulation interacts with aggressive temperament to increase the likelihood of aggressive action.
Viewing aggression affects beliefs and values.	Aggressive behavior is seen as an acceptable way to resolve conflicts. Viewers are hardened to the use of aggression in peer interactions. Aggression is used as a response to frustration. Viewers expect others to be aggressive toward them. Viewers worry about being victims of aggression. Viewers see the world as a dangerous place.

© Cengage

is rewarded or viewed as successful because of violent actions, children's tendencies to express aggression are increased.

Second, exposure to media violence has an impact on the neurological system. Watching media violence produces a heightening of arousal (Simons et al., 2003). The fast action that usually accompanies televised violence captures the viewer's attention. Watching this fast-paced programming has an effect on a young child's executive functioning. Experimental studies find that immediately after watching fast-paced programs, children have more trouble with self-regulation, delay of gratification, and focused attention (Lillard & Peterson, 2011). Watching a violent incident raises the child's level of emotionality, bringing to the fore other aggressive feelings, thoughts, memories, and action tendencies. The more frequently this network of elements is activated, the stronger their association will be. In some video games, the child selects a character and is encouraged to identify with that role. Violent acts are repeated over and over, with the possibility that the child increases the character's aggressive behaviors after each encounter, thereby escalating the level of emotional intensity and angry feelings as the play continues (Bushman & Anderson, 2002). Particularly for children who are temperamentally aggressive, watching violent television or playing violent video games increases their inclination toward aggressiveness in real-life situations (Wittman, Arce, & Santisteban, 2008).

Finally, exposure to media violence affects a young child's beliefs and values. Children who are exposed to frequent episodes of televised violence are more likely to believe that aggressive behavior is an acceptable way to resolve conflicts, and they become hardened to the use of aggression in peer interactions. They are also more accepting of the use of aggression as a response to frustration. Children (and adults) who are exposed to media violence are more likely to expect that others will be aggressive toward them, worry about being victims of aggression, and see the world as a dangerous place (Huesmann & Skoric, 2003).

Exposure to media violence has long-lasting effects. For example, in a longitudinal study, TV viewing habits in childhood (ages 6 to 10) were related to adult aggressive behavior 15 years later. The relationship between extensive exposure to televised violence in childhood and later aggressive behavior was observed for both men and women, even after controlling for mitigating factors such as intelligence, parenting characteristics, and family's socioeconomic status. The more children identified with aggressive TV characters, the stronger this relationship to adult aggressive behavior (Huesmann, Moise-Titus, Podolski, & Eron, 2003).

Prosocial Programming. If watching media violence can influence aggressive behavior, it makes sense to think that watching positive, prosocial behaviors can influence caring, helping, and other positive behaviors. One analysis found that in a week of television programming of over 2,000 shows, 73 percent included one act of altruism defined as helping, sharing, giving, or donating. Children's programming includes more frequent instances of prosocial behavior. A child who watches an average of three hours a day of children's television programming will see 4,380 acts of altruism a year (Wislon, 2008).

Children who are exposed to prosocial programming are influenced toward more positive social behavior. One study recontacted more than 500 adolescents whose television viewing had been studied when they were in early childhood. Watching educational programming in the early years was associated with many positive characteristics in adolescence, including higher grades, reading more books, greater creativity, and less aggression (Anderson, Huston, Schmitt, Linebarger, & Wright, 2001). In a meta-analysis of 34 studies on the prosocial effects of watching television, a clear relationship was observed between watching prosocial programming and children's positive behaviors including altruism, positive social interactions with others, and tolerance for differences (Mares & Woodard, 2005). The positive impact of these programs can be enhanced when adults and children talk about the moral message of the episode or about how the positive behaviors might be enacted in other situations. Other studies considered the relationship between playing prosocial video games, that is, games that include opportunities for characters to help one another or form friendships, and the players' real-life prosocial behaviors. There was a consistent relationship between time spent playing prosocial games and prosocial behaviors such as helping someone, cooperation and sharing, empathy, and emotional awareness (Gentile et. al., 2009).

Many programs—some developed for children and others intended for a broader viewing audience—convey positive ethical messages about the value of family life, the need to work hard and sacrifice in order to achieve important goals, the value of friendship, the importance of loyalty and commitment in relationships, and many other cultural values. A number of contemporary programs include characters of many races and ethnic backgrounds. Many feature women in positions of authority or performing acts of heroism. Increasingly, programs include characters with physical disabilities who play important roles. Through exposure to these programs, children learn to challenge social stereotypes and develop positive images of people from many ethnic groups (Rosenkoetter, 1999).

Review of Influences on Moral Development

In early school age, children are developing an initial moral code. The approaches to this issue are summarized in Table 7.3. Each contribution highlights an essential element of the larger, more complex phenomenon. *Learning theory* points out that an external reward structure inhibits or reinforces behavior. *Cognitive theory* suggests that in early childhood, children are most likely to take a pragmatic view about whether something is right or wrong, based largely on the consequences. *Psychoanalytic theory* is especially concerned with the relationship between parental identification and the development of conscience. O*bject relations theory* stresses the importance of early, loving relationships with a sensitive caregiver as the path through which a child comes to value the self and to care about others. *Evolutionary theory* highlights benefits to groups that were able to create moral codes that emphasize protecting the kin from harm, behaving fairly and exercising reciprocity, being loyal to members of one's group, showing respect and obedience to authority, and maintaining bodily and spiritual purity.

Table 7.3 Contributions to the Study of Moral Development

Conceptual Source	Significant Contributions	Relevance for a Particular Aspect of Moral Development
Learning theory	Relevance of an external system of rewards and punishments. Imitation of models. Formation of expectations about the reward structure.	Moral behaviors. Internalization of a moral code.
Cognitive theory	Conceptual development of notions of intentionality, rules, justice, and authority. Stages of moral reasoning.	Moral judgments. Distinctions between moral transgressions and social convention transgressions.
Psychosexual theory	Parental identification. Formation of the superego and the ego ideal.	Internalization of parental values and moral standards. Experiences of guilt.
Object relations theory	The origins of morality in infancy with the development of object relations. The extension of self-love to love of the other and the desire to maintain connection with loved others.	Moral emotions. Formation of strong ties between self and others. Willing compliance with adult requests.
Evolutionary theory	Adaptive nature of moral intuition and moral reasoning. Morality as co-evolving with large cultural groups. Moral standards promoting the cohesiveness and stability of the group.	Moral emotions. Content of moral principles and their relationship to group survival.
Research on empathy, care, and perspective taking	Ability to experience another's feelings begins very early and changes with age. Care, the feelings of concern and desire to help, emerge early and continue to mature along with increases in cognitive development. Ability to recognize differences in point of view emerges slowly during early-school-age and middle childhood years.	Empathy heightens concern for others and helps inhibit actions that might cause distress. Perspective taking can foster helping and altruism. A caring orientation influences action—a willingness to reduce distress and provide help.
Research on parental discipline	Parents define moral content. Parents point out the implications of a child's behavior for others. Parents create a reward structure.	Standards for moral behavior. Moral reasoning. Internalization of moral values.
Research on media	Observing aggressive role models. Arousal of aggressive emotions, memories, and action tendencies. Formation of beliefs and values about the use of aggression to resolve conflict. Prosocial thoughts and behaviors can be stimulated.	New repertoire of aggressive behaviors. Lower threshold for aggressive actions. Expectations of aggression from others. Desensitization to acts of violence. Imitate models of prosocial behavior. Reduce aggressive behaviors and increase helpfulness.

© Cengage

The research on *empathy, care,* and *perspective taking* shows that moral behavior requires an emotional and cognitive understanding of the needs of others as well as a desire or even a sense of obligation to help. Research on *parental discipline* suggests that parents promote moral development when they establish clear standards, involve their children in dialogue, and try to increase children's understanding of the effects of their behavior on others. Research on *media*, including television and video games, shows that children who are exposed to many hours of violent programming or who engage in many hours of violent video game play are more likely to act aggressively, accept violence as a method for resolving conflicts, and interpret the behavior of others as having an aggressive intention. In contrast, watching prosocial programming can have a positive impact on young children's altruism and positive interactions with others.

FURTHER REFLECTION: *What are your earliest recollections of your own moral development? What did you consider to be the essential "rights" and "wrongs" when you were very young? What difficulties did you face in trying to live up to the moral standards that were impressed upon you at that time?*

What were the early influences on your moral code? Can you recall any stories, television programs, movies, books, or other cultural resources that shaped your sense of right and wrong?

Self-Theory

OBJECTIVE 3 Analyze changes in the self-theory, with special focus on the theory of mind and self-esteem during the early-school-age years.

The development of the self-concept is at the heart of psychosocial development. Psychosocial theory provides a framework for understanding how the ego is transformed through ongoing interactions with society over the life span. It describes the creative process through which basic experiences of the physical self in infancy are transformed through self-awareness, self-consciousness, self-control, a sense of self—other relationships, a personal identity, a style of life, and finally a sense of integrity about the life one has lived.

The self-concept can be viewed as a theory that links the child's understanding of the nature of the world, the nature of the self, and the meaning of interactions between the two (Epstein, 1973, 1991, 1998). Consider the two cases of Gloria and Lee. We see two very distinct approaches to the construction of a self-theory. Gloria is reserved; she takes refuge in her closet to read and pretend; she feels proud of her independence, but reluctant to face the adult world. Issues of race and discrimination enter into her sense of self at a very young age, creating a degree of cautiousness. Lee is rambunctious; she loves the outdoors; her fantasies are of adventure and daring; she is aware of the restrictions of the adult world, but they do not seem to worry her. Although she knows she is a girl, she aligns herself with the male world in scorning girls.

The function of the **self-theory** is to make transactions between the self and the world turn out as positively and beneficially as possible. One's theory about oneself draws on such inner phenomena as dreams, emotions, thoughts, fantasies, and feelings of pleasure or pain. One's self-theory is also based on logical thoughts and information such as assessments of one's abilities, comparisons with others, and analysis of experiences with the environment (Epstein, 2003, 2008). The complexity and logic of the self-theory depend on the maturation of cognitive functions, which is tied in part to the maturation of the brain. Furthermore, because the self-theory is based on personal experiences and observations, one would expect it to be modified over the life course as a result of changing physical, cognitive, and socioemotional competencies as well as by participation in new roles.

The Neuroscience of the Self

The self-concept is a complex construction based on many sources of information including one's physical appearance, an awareness of one's body, the sound of one's voice, memories of one's past experiences and the emotions tied to those experiences, current thoughts and feelings, one's tastes and preferences, hopes and dreams about one's future, and a wealth of information coming from others about how you are perceived and what is expected of you. Neuroscientists are striving to understand how the brain manages to integrate all these facets into a coherent sense of self (Morin, 2006).

The brain appears to have at least four functions that contribute to components of the self-concept:

1. Recognition and experiences of the physical self.
2. Self-representations. This includes use of personal pronouns, experiences of ownership ("mine"), awareness of one's personality traits and preferences, and self-appraisal (self-esteem).
3. Awareness of the expectations of others for oneself. Judging how you measure up to the expectations and social standards of others.
4. Awareness of the differences between the self and others. Distinguishing one's own thoughts and feelings from the thoughts and feelings of others; the "me" from the "not me."

Each of these four functions is associated with specific areas of the brain. Work by Uddin, Iacoboni, Lange, and Keenan (2007) suggests that there are two separate but interrelated areas that support the capacity for distinguishing the self and others, self-representation, and the ability to understand and learn from others. The right frontoparietal area is active when individuals view their own face as compared to faces of familiar others. This same area is also active in response to images of one's body and the sounds of one's voice. So it appears that the right frontoparietal area is involved in many of the physical aspects of the self-concept. This area overlaps with an area of the mirror neuron system described in chapter 6. The mirror neuron system supports the ability to understand and replicate the actions and goals of others (Neiworth, 2009).This helps explain how a child can observe and imitate the behaviors of others and then incorporate those behaviors into their own physical/motor patterns.

Other brain regions are associated with self-representations including self-recognition, use of personal pronouns, expression of ownership, self-appraisal, judging one's personality traits, and making judgments about the mental states of others (Lewis & Carmody, 2008). This brain structure (the cortical midline structure) is activated when the person is integrating information in order to make judgments about the self (Northoff & Bermpohl, 2004). As one might expect, these areas of the brain are interconnected, sending information back and forth so that experiences of viewing one's image and thinking about oneself form an integrated concept. The convergence and interaction of these brain areas with the mirror neuron system contribute to the ability for self-recognition, self–other distinctions, the ability to replicate another person's actions and understand the intentions of those actions, and the ability to reflect upon another person's experiences and perceptions in comparison to our own (Ruby & Decety, 2001, 2004).

This research, which considers the neural basis for self-concept, supports the underlying principle from psychosocial theory of an ongoing interaction between the person and the social environment. At the neural level, a variety of mechanisms operate to connect information about the self and others. As self-awareness and self-understanding mature, so does awareness of and understanding of the other.

In the sections that follow, the self-theory is discussed in relation to the distinction between the *me* and the *I*, a general description of how the self-theory changes from infancy through middle childhood, and the nature of self-esteem—the evaluative aspect of a child's sense of self.

The Me and the I

One of the earliest psychological analyses of self-theory was provided by William James (1892/1961). He described two elements of the self, the *me* and the *I*. The *me* is the self as object—the self one can describe—including physical characteristics, personality traits, social roles and relationships, thoughts, and feelings. The *I* is the self who is aware, the self that feels, knows, and plans one's actions. It can be characterized by four features: (1) a sense of agency or initiation of behaviors; a sense of voluntary action or free will; (2) a sense of uniqueness; (3) a sense of continuity from moment to moment and from day to day; and (4) an awareness of one's own awareness (i.e., metacognition).

Building on these ideas, Damon and Hart (1988) devised a model of self-understanding that includes both the *me* (*self as the object of awareness and as perceived by others*) and the *I* (*self as the subject, the one who experiences and knows*) changing over time. The Me, can be characterized along four dimensions: *physical self* (my physical appearance and observable characteristics), *active self* (my behaviors and actions), *social self* (my social bonds and social skills), and *psychological self* (my personality, emotions, and thoughts). The I, or self as subject, can be characterized along three dimensions: *continuity* (experiences that allow me to know that I am the same person from day to day), *distinctiveness* (experiences that illustrate how I differ from others and perceive myself to be a unique individual), and *agency* (experiences that allow me to believe that I have an impact, that I am a causal agent). At each stage of development from early school age through later adolescence, these seven dimensions of self-change.

One can recognize evidence of self-understanding in each domain even in early childhood. Development of the self is not viewed as a shift in awareness of the physical self in childhood to an awareness of the social self at a later age. Rather, there is a continuous awareness of the physical self, but the way it is evaluated and assessed changes as other aspects of the I and Me change. Self-understanding is transformed from a *categorical* and concrete assessment of the self in early school age to a *comparative* assessment of self and others in middle childhood. This is followed by a shift to an understanding of the *social implications of one's self-characteristics* in early adolescence. In later adolescence the organizing principle becomes the formulation of a *personal and social identity* that integrates the characteristics of the self into a set of beliefs and plans that guide future actions. By later adolescence, aspects of the self-theory, including personal values, experiences, and interpretations of life events, shape and are shaped by interpersonal relationships and moral choices.

Developmental Changes in the Self-Theory

The self-concept, including the I and the Me, is a product of a person's cognitive capacities and dominant motives as he or she comes into contact with the stage-related expectations of family, peers, teachers, and other members of the radius of significant others (Harter, 2012). As a result, one can expect the self-concept to undergo developmental changes, brought about in part by changing cognitive capacities and in part by changing societal messages the child encounters at various periods of life.

In infancy, the self consists of a gradual awareness of one's independent existence. The infant discovers body boundaries, learns to identify recurring need states, and feels the comfort of loving contact with caregivers. Early efforts to reach and grab objects suggests an awareness of the distinction between the self and the other. Early gestures, like showing and pointing, offer additional evidence of the infant's awareness of this distinction (Rochat, 2012). Basic needs to maximize pleasure and avoid pain and to preserve closeness to the loving caregiver serve as organizing principles for the infant's behavior. Many theorists emphasize the close connection of the infant's internal working model of the self with the responsiveness of the other (Bretherton & Munholland, 2010). The infant relies on the other to be accessible, to permit exploration, and to comfort and reassure.

During the second year of life, self-recognition and the sense of the self as a causal agent add new dimensions to the self-theory. Gradually, these experiences are integrated into a sense of the self as a permanent being who has an impact on the environment, existing in the context of a group of other permanent beings who either do or do not respond adequately to the infant's internal states.

In toddlerhood, the self-theory grows through an active process of self-differentiation. Children explore the limits of their capacities and the nature of their impact on others. Because of toddlers' limited ability to entertain abstract concepts and their tendency to perceive themselves as the center of the world, their self-theories are based largely on the accumulation of daily experiences of competence, self-directed goal attainment, and praise

manzrussali/Shutterstock.com

Claude is fascinated by his image reflected in the water. He notes his facial features and enjoys his appearance. His self-concept is emerging as he begins thinking about who he is, what he is like, and what the future holds for him.

or disapproval. There is little recognition of social comparisons (being better or worse than someone else), but an increasing sensitivity to the positive and negative reactions of others. Emotions including embarrassment and shame suggest an emerging awareness of the self as an object that is perceived by others.

During early school age, the self-theory becomes more complex. Children can distinguish between the real self (how one actually is) and the ideal self (how one would like to be). They recognize some discrepancies between how they describe themselves and how their parents or friends may describe them (Burton & Mitchell, 2003). They can differentiate among various areas of activities like math, reading, and music, indicating perceptions of strength in certain areas and weakness in others (Denissen, Zarrett, & Eccles, 2007).

According to Damon and Hart (1988), in early school age the self is understood as an accumulation of **categorical identifications**. No additional linkage or significance is taken from these categorical statements—simply a recognition that they exist.

> EXAMPLES: What kind of person are you? *I have blue eyes.*
>
> Why is that important? *It just is.*
>
> What kind of a person are you? *I'm Catholic.*
>
> What does that say about you? *I'm Catholic, and my mother is, and my father is, and my grandmother, and my grandfather, and I'm Catholic too.*
>
> (pp. 59–60)

In middle childhood, the organizing principle shifts to **comparative assessments**. Self-understanding relies on comparisons of oneself with social norms and standards or with specific other people.

> EXAMPLES: What are you like? *I'm bigger than most kids.*
>
> Why is that important? *I can run faster than everybody.*
>
> What are you like? *I'm not as smart as most kids.*
>
> Why is that important? *It takes me longer to do my homework.* (pp. 62–63)

The period of early school age brings with it heightened self-consciousness. Through conversations, stories, photographs, and rituals, early-school-age children begin to understand that their experiences have a uniqueness. With increasing capacities for perspective taking, children can appreciate that their view of themselves may differ from the view that others have of them. They realize that they exist in a specific time, not in the long ago of dinosaurs or pioneers, nor in near past of their grandmother's or their mother's childhood (Nelson, 2000). The ability to reflect on the self in the past and the self in the present contributes to a new aspect of the self-concept, bringing with it both the comfort of a sense of self-sameness, and the beginnings of an appreciation for the ability to change and grow. It is not uncommon for children in early school age to begin reflecting on what they hope to be when they grow up, a kind of speculation that links a self-appraisal of their strengths and interests with an understanding of the social positions that might be possible in their culture (D'Argembeau et al., 2008).

Kablonk/Golden Pixels LLC/Alamy Stock Photo

In order to collaborate on a project, children need to be able to take the point of view of the other person. As the self-concept matures, so does the ability to think about how situations may appear to someone else.

Culture and the Self-Theory

Certain aspects of culture influence the nature of self-concept. In many Western countries, values given to characteristics such as self-reliance, autonomy, and distinctiveness shape a relatively more *independent* view of the self. In many Asian cultures, values given to fitting in with the group and preserving harmonious relationships shape a relatively more *interdependent* view of the self. In both cultural views, individuals are able to differentiate a sense of self and other. They are aware of a continuous self who is the same today as yesterday and can make distinctions between a view of an inner or private self and a public self. However, in the independent orientation, greater emphasis is placed on an inherent distinctiveness in which the self is the figure and others are the ground. In the interdependent orientation, a greater emphasis is placed on the inherent interconnectedness of members of the group and an appreciation that one's thoughts, feelings, and behaviors fluctuate based on the desire to fit in to the larger social unit.

For example, one study reported on U.S. and Chinese college students' earliest childhood memories (Wang, 2001). The average age for these first memories was 3½ years for U.S. students, and 4 years for the Chinese students. The U.S. students' memories tended to be discreet events where they had the lead role in a drama or some emotional event or moment. The Chinese students' memories tended to be more routine events involving family and neighborhood. Students were asked to produce something that they actually remembered, not something someone had told them.

The following is a U.S. college student's response to a request to think of her earliest memory and to describe it as precisely as possible. This memory comes from a time when the student was about 3.

> I remember standing in my aunt's spacious blue bedroom and looking up at the ceiling. Then something caught my eye—it was the white wainscoting that bordered the top of the wall with the ceiling. I remember staring, fixated with its intricate design. And while I was doing this, all of sudden, I had an epiphany, a sort [of] realization. It was almost my first realization of a sense of "self." Because, as I was staring at the ceiling,

> I realized that no one else was around. I remember being taken aback by the ability to amuse myself without any toys. (Wang, 2001, p. 220)

The next childhood memory was told by a Chinese female college student from the time when she was about age 5.

> I was 5 years old. Dad taught me ancient poems. It was always when he was washing vegetables that he would explain a poem to me. It was very moving. I will never forget the poems such as "Pi-Ba-Xing" one of the poems I learned then. (Wang, 2001, appendix)

Cultural worldviews are preserved in each society's view of the self. In the United States, the self is valued as a unique, bounded, autonomous being that guides the life history through choices and action. In China and in other Asian cultures, the self is viewed as an interdependent, relational being. In these cultures, children are encouraged to show restraint in their interactions with certain others, particularly in public situations, in order to preserve social cohesion. Whereas self-expression may be encouraged in private, self-control is valued in public (Raeff, 2010). As we think about the emergence of a self-theory in early school age, it is important to keep in mind that cultures not only shape the value placed on certain attributes but also influence whether children are likely to think of the self as relatively stable and enduring across settings or relatively fluid and attuned to the demands and expectations of the social situation.

Self-Esteem

For every component of the self—the physical, emotional, social, and psychological self—a person makes an evaluation of worthiness. This self-evaluation, or **self-esteem**, is based on three sources: (1) messages of love, support, and approval from others; (2) specific attributes and competencies; and (3) the way one regards these specific aspects of the self in comparison with others and in relation to one's ideal self. The need to protect and enhance one's self-esteem is a basic psychological motive that drives behavior (Greenberg, 2008). Views of the self as being loved, valued, admired, and successful contribute to a sense of worth. Views of the self as being ignored, rejected, scorned, and inadequate contribute to a sense of worthlessness. These early affective experiences build a general sense of pride or shame, worthiness or worthlessness that is captured in the global statements children make about themselves even as early as age 3 or 4.

michaeljung/Shutterstock.com

Experiences of success build confidence and contribute to positive self-esteem.

Information about specific aspects of the self is accumulated through experiences of success and failure in daily tasks or when particular aspects of one's competence are challenged. A young child may develop a positive sense of self in athletics, problem solving, or social skills through the encouraging reactions of others as well as through the pleasure associated with succeeding in each of these areas (Harter & Bukowski, 2012).

With experience in a variety of roles and settings, each specific ability takes on a certain level of importance. Not all abilities are equally valued at home, at school, and by friends. Children may believe they have abilities in some areas, but not in those they consider highly important. Others may believe they have only one or two areas of strength, but they may highly value those areas and believe them to be critically important to their overall success. Self-esteem is influenced by the value one assigns to specific competencies in relation to one's overall life goals and personal ideals. Thus, it is possible to be a success in the eyes of others and still feel a nagging sense of worthlessness. Similarly, it is possible to feel proud and confident even when others do not value the activities and traits in which one takes satisfaction.

Feelings of positive self-worth provide a protective buffer against insecurity or conditions that threaten to expose one's lack of value or meaning. If a person has a positive, optimistic self-evaluation, then messages that are negative and incongruent with it will be deflected. People with high self-esteem may explain a failure by examining the task, the amount of time needed for its completion, the other people involved, or the criteria for evaluating success and failure. They use strategies to minimize the importance of negative feedback. They do not permit a failure to increase doubt about their basic worth. Rather, their high self-esteem functions to protect their positive self-evaluation by coping effectively with negative feedback and reclaiming their view of the self as someone who has socially valued qualities (Brown, Dutton, & Cook, 2001).

By contrast, people with low self-esteem feel worse after a failure, tend to view failure as new evidence of their lack of worth, and are less likely to cope effectively with the negative feelings that accompany failure (Heimpel, Wood, Marshall, & Brown, 2002). People with low self-esteem appear to accept negative moods that follow a failure experience and are less likely to take action to try to improve their mood. Because negative feedback is so painful for those with low self-esteem, they avoid unfavorable comparisons with others, leading them to be more cautious in situations that might expose them to criticism (Bernichon, Cook, & Brown, 2003).

Despite the many positive correlates of high self-esteem, some question whether high self-esteem is always a positive quality. Some researchers have suggested that there is such a thing as

Monkey Business Images/Shutterstock.com

By the age of 5 or 6, children are trying hard to gain acceptance from adults and peers. Even mild criticism from a teacher is often enough to arouse feelings of guilt or remorse. What kind of teacher criticism do you imagine might be taking place in this photo?

unrealistic or fragile high self-esteem (Kernis, 2003). For example, people with high self-esteem seem to deflect failure messages in one area by emphasizing their abilities in another area. When employed consistently, this strategy can be perceived as a defensive reaction that allows the individual to preserve a sense of self-worth rather than to address underlying feelings of inferiority or shame (Jordan et al., 2003).

A different criticism concerning self-esteem is that the emphasis on high self-esteem is a value that reflects the individualist nature of Western culture. In contrast, Eastern cultures are less concerned with affirming the positive qualities of the individual, valuing instead self-discipline and self-improvement (Markus, Mullally, & Kitayama, 1997). A pan-cultural perspective suggests that it is a universal tendency for humans to strive for and protect their self-regard. However, the norms for what one considers evidence of self-worth and the strategies that human beings use to advance their self-regard are shaped by culture (Brown, 2003; Sedikides, Gaertner, & Toguchi, 2003; Sedikides, Gaertner, & Vevea, 2005).

A third concern is the confusion between self-esteem and narcissism. Both of these personality qualities arise as children internalize how other people perceive them. Whereas some scholars suggest that narcissism is an excessive expression of self-esteem, others suggest that these two traits are quite distinct. Narcissists feel superior to others; they believe they should be entitled to special treatment, respect, and privilege. Those with high self-esteem feel satisfied with themselves and confident in their abilities; they view themselves as worthy but not superior to others (Brummelman, Thomaes, & Sedikides, 2016). Socialization messages that express affection and appreciation nurture self-esteem, whereas messages that over value the child or convey that the child is superior to others can nurture narcissism (Brummelman et al., 2015).

Self-Esteem and the Early-School-Age Child. At each life stage, as individuals set new goals for themselves or as discrepancies in competence become apparent, temporary periods of lowered self-esteem may be anticipated. Although we tend to think of self-esteem as a stable trait that characterizes individuals across settings, there are periods of life when self-esteem is more vulnerable to fluctuation, especially as individuals encounter dramatic changes in roles, environments, and normative expectations for behavior (Trzesniewski, Donnellan, & Robins, 2003). Early childhood appears to be one of those periods.

The family provides a critical context that can support or undermine a child's self- esteem. When parents speak in a positive way to their children, recall positive emotions and experiences, and offer explanations even when they are engaged in conflict with their children, the children have a more positive self-esteem (Reese, Bird, & Tripp, 2007). When parents make unfavorable comparisons of their child to other siblings or peers, or when they highlight shortcomings and make repeated reference to negative experiences and emotions, these interactions lower the child's self-esteem.

In early school age, children are increasingly able to make distinctions among areas of competence, such as math ability, reading, writing, athletic ability, or artistic or musical talents. They may also think that some aspects of competence are more important than others, and they are able to judge their own abilities in light of what they believe others expect of them. When children think an area is important and they believe they are competent in that area, it increases their self-esteem. When children think an area is important and they believe they are not very competent in that area, it decreases their self-esteem (Grier, 2013).

Children are also aware of the importance of acceptance by adults and peers outside the family, especially their teachers and classmates. When students have opportunities to present their work, or when their work is displayed in a personalized way in the classroom, it tends to increase their feelings of self-worth. In contrast, when teachers or children tease or belittle each other in the classroom, it has a negative impact on self-worth (Maxwell & Chmielewski, 2008).

In addition to the influences of families and school environments on self-esteem, young children are aware of the expectations and stereotypes conveyed by their peers and the media about body type and physical appearance. In a study of girls ages 5 through 8, the expression among peers about the desire to be thin and exposure to television programming that promoted the value of thinness was shown to promote body dissatisfaction. As the girls were followed over the course of a year, from age 5 to 6 or 6 to 7, body dissatisfaction in the first year was found to predict lower self-esteem 1 year later (Dohnt & Tiggemann, 2006). Even at this very young age, children are reacting to social messages about physical appearance that can negatively impact their feelings of self-worth.

Children's sense of self-esteem begins to crystallize in the early-school-age years. In research with kindergartners, children were faced with a challenging task. The way children approached the task, their hopefulness about succeeding, and their general expression of positive or negative attributes were combined to reflect a measure of helplessness. Five years later, the expressions of helplessness assessed in kindergarten proved to be a good predictor of depression and a low sense of self-worth. A scheme for low self-esteem and helplessness may begin to take shape in the early childhood period and, unless challenged through positive intervention, may color a child's sense of mastery and competence in the years ahead (Davis-Kean & Sandler, 2001; Kistner, Ziegert, Castro, & Robertson, 2001). Young children need frequent reassurance from adults that they are competent, safe, and loved. They need numerous opportunities to discover that their unique talents and abilities are useful and important and that they can have a positive impact on others. As competencies increase, as thought becomes more flexible, and as the child makes meaningful friendships, self-esteem is expected to increase.

FURTHER REFLECTION: *Analyze the interaction of the developmental tasks of gender identification, moral development, and self-theory. How might gender identification and moral development influence a child's self-theory? How might a child's self-theory influence their gender identification and moral development?*

Peer Play

OBJECTIVE 4 Describe the features of peer play, including group games, media play, and friendship in the early-school-age years.

Although experiences in the family provide the primary information that guides a young child's construction of the social world, interactions with peers contribute important opportunities for physical, cognitive, social, and emotional development. The quality of play expands during the early-school-age period, introducing more complex games with larger numbers of participants. Media in various forms have increasingly become play companions. Children form friendship groups that allow them to sustain more elaborate fantasy play, experience group cooperation and conflict, participate in group problem solving, and encounter varying ideas about the topics discussed previously: gender, morality, and the self.

Developmental scholars generally acknowledge the value of child-initiated, freely chosen play for the young child's cognitive and social development. Nonetheless, playtime at school and at home is dwindling. Estimates suggest that young children have 8 fewer hours a week of unstructured play time today than did children 20 years ago (Elkind, 2007; Miller & Almon, 2009). With the upward pressure on kindergarten and first grade to introduce new levels of competence in basic academic skills, there are fewer resources and less time available for child-initiated play. Outside of school, many families create a series of structured activities for their young children including music lessons, early sports experiences, and language enrichment, leaving little time for after-school or weekend unstructured play.

What is more, the toys and play resources that are marketed for young children are becoming increasingly oriented toward specific educational objectives such as vocabulary building and math facts. Through the insertion of computer chips, the play value of many modern toys is controlled in advance by the manufacturers rather than invented through the child's active exploration (Winerman, 2009). In the following sections we focus on group games, media play, and friendships as aspects of peer play in early school age.

Group Games

Early-school-age children continue to use vivid fantasies in play. However, during this period a new form of play emerges. Children show interest in **group games** that are more structured and somewhat more oriented to reality than social pretend play based primarily on imagination. Duck-Duck-Goose, London Bridges, and Farmer-in-the-Dell are examples of early group play. Simon Says, Hide-and-Seek, Hopscotch, and Statue-Maker are more complex games of early school age. They involve more cognitive complexity, physical skill, and ritual. These games combine fantasy with an emphasis on peer cooperation and competition. Group play is a transitional form between the fantasy play of the toddler and the team sports and other games with rules of middle childhood (Erikson, 1977).

Group games usually include a few rules that are simple enough so that a child can use them effectively to begin a game and determine a winner without the help of an adult. Usually, no team concept is involved. A game is played repeatedly so that many children have an opportunity to win. The particular pleasure that children derive from these games seems to result more from peer cooperation and interaction than from being a winner. Many of these games permit children to shift roles. A child is the hider and then the seeker, the catcher and then the thrower, the statue-maker and then the statue. Through group play, children experience the reciprocal nature of role relationships. Whereas many of their social roles are fixed—son or daughter, sibling, student—in play with peers, children have opportunities to experience a variety of perspectives.

Early-school-age children also play simple board games that involve two or more players. Games like Chutes and Ladders, Checkers, Candyland, Hi Ho Cherry-o, and card games like War and Go-Fish give young children opportunities to experience games with a few rules that set the stage for later, more complex play. These games introduce the idea of winning and losing. They typically combine elements of chance and a bit of skill, giving young children the idea of having good or bad luck. By the age of 5 most children understand that games involve both cooperation and competition. Cooperation is reflected in the willingness of the players to take turns and follow the rules. Competition is reflected in using one's best chances and strategies to win (Schmidt, Hardecker, & Tomasello, 2016). Once they understand about winning and losing, it is not unusual for early-school-age children to make up their own rules or ignore the rules in order to win.

Media Play

From a psychosocial perspective, development is a product of the ongoing interaction of the changing person in a changing environment. The media environment is an excellent example of this idea. Children are being exposed to electronic media at younger and younger ages, and new media platforms and resources are being developed for this young audience. A research literature is accumulating about the scope and extent of use of these electronic media by very young children and its impact on their social and cognitive development (Dill, 2009; Strasburger, Wilson, & Jordan, 2014).

A national survey sponsored by Common Sense Media was designed to address questions about young children's use of diverse media. How much time do children spend with electronic media including television, computers, video games, and mobile devices? How many children have access to new mobile media devices? What types of activities/content do children engage with using various media platforms (Rideout, 2013)? The study involved a nationally representative sample of families with children ages 0 to 8 years old. Survey responses were given by parents.

Children spent an average of 2 hours a day with some type of screen media. Television was the dominant media source; almost all the children (96 percent) had TVs in their homes and about half the daily screen time was spent watching television. Television is a major source of educational content, especially for 2- to 4-year-olds. Older children are more likely to watch children's entertainment programs. However, an increasing amount of this viewing (about one third) is spent watching programming that was recorded earlier, downloaded, or accessed on demand. In 38 percent of homes, the TV is on most or all of the time even if no one is watching. Over half the parents say that they sometimes or often have their children with them while they watch their own programs.

Children are not just passive consumers of electronic media—they are making choices and affecting their media environment. Table 7.4 shows the percentage of children ages 0 to 8 who use each type of resource on a daily basis. Of particular note is the increasing use of mobile media (smartphones and tablets). Almost three fourths of children have used a mobile device at some time, and 17 percent use one daily. For those who use one daily, the time spent was slightly over one hour. Surprisingly, even among the youngest children (0–2), parents report that 38 percent have used a mobile device. By the age 5 to 8, over 80 percent have used a mobile device, especially for playing games, and also for use with apps that involve creative art, music, photography, and as an e-reader.

Income Inequality and Media Access

The Common Sense Media survey divided the sample into three income groups: low-income ($30,000 and under), middle income ($30,000–$75,000), and higher income ($75,000 and above). Media use and access differ by income. Low-income families are less likely than high-income families to have high speed internet (46 percent versus 86 percent). As a result, in many homes children's access to media content is limited to broadcast, real-time programming. Low-income families are more likely to have the television going when no one is watching, and children in low-income families are more likely to have a television in their room. Parents say that a common reason is that the young child shares a room with an older sibling, an adult, or sleeps in a common bedroom. This means that children in lower-income families are more likely to be exposed to the programming and advertising that was intended for adult viewers. Although ownership of smartphones and tablets has been increasing, there is still a gap between low-income and higher income families (smartphone: 25 percent gap; tablet: 43 percent gap). As a result, fewer low-income families have downloaded an educational app or any type of child-orientated app to a smartphone or tablet. Even among low-income families that have a mobile device, fewer parents have downloaded educational apps for their children than among middle and higher-income families.

Table 7.4 **Daily Media Activities**

Among 0- to 8-year-olds, the percent who engage in each activity at least once or more per day	
Read/are read to	60%
Watch TV	58%
Watch DVDs	18%
Use a mobile device*	17%
Use a computer	14%
Use handheld video game	7%
Use console video game	6%
Read an ebook	4%

* Such as a smartphone or tablet

Source: Rideout, 2013, Table 4. p. 16.

The media is an intimate part of family life. Various media are used by families in different ways, for play, learning, escape, to foster interactions, and to give parents a time when they are not interacting with their children.

> Being an adult is hard. There are times when my interacting with my children is best served by me having an opportunity to allow them to do something alone so I can regroup. When I got laid off a couple of weeks ago, I didn't know it was coming. I got blindsided. I couldn't have interacted with my children that night. I couldn't have done it. "Let's watch *Finding Nemo,* kids. Here are some chicken strips, here are sippy cups—I'll see you in about an hour and a half." (Rideout, Hamel, & Kaiser Family Foundation, 2006, p. 14)

Many videos, computer programs, and video games are marketed to parents as having an educational value. However, manufacturers argue that their first concern is that the materials have to be fun. They believe that if children don't experience the materials as fun, then the media won't be used and the educational value will never be realized. Parents seem to be divided in their views about the educational value of television and other media. Some are surprised about the positive things their children take away from watching TV. "My daughter started saying something to me in Spanish—I don't know a word of Spanish—TV is definitely educational" (Rideout, Hamel, & Kaiser Family Foundation, 2006, p. 14). At the same time, families appear to be setting more rules about how much television their children can watch and what types of video games, mobile apps, or hand held games they can play, implying some wariness about the impact of these resources on their children's emotional and cognitive development. A systematic review of the evidence found few if any published studies that document the advertised educational claims associated with these resources (Garrison & Christakis, 2005).

Children's media games seem to share certain features. The most popular games are action or combat scenarios, sports, and adventure games. At every age, boys spend more time playing media games than girls (Cherney & London, 2006; Rideout, 2013). That may be explained in part by the fact that most of the player-controlled characters in the most popular video games are male. Where female characters appear, they tend to be in supportive or helping roles (Mou & Peng, 2009). Boys may also be more interested in the themes that dominate many video games, especially sports, combat, and monster scenarios.

Studies that focus on the design features of interactive games find that experience with these games contributes to spatial visualization, visual attention, manual dexterity, and early readiness for computer literacy (Subrahmanyam, Kraut, Greenfield, & Gross, 2001). Most of the video games require some reading skills. Speed of response is a feature of many games. This rewards children who can think quickly, analyze the situation, and make a rapid-fire motor response. When you lose or the turn ends, it is easy to start over and try to do better the next time. Many of the games provide immediate reinforcement through increasing points, sounds, accumulation of virtual rewards, and access to new screens or levels. In some games, children can play with or against each other.

Studies of video game use among young children suggest that children link their experiences with television, videos, and video games into other areas of imagination and creativity. It is not unusual for children to form relationships with the on-screen characters, which seems to lead to increased motivation to pay attention to the information that these characters present and to learn from them (Richert, Robb, & Smith, 2011). The media themselves are often linked so that characters from a movie or television program are integrated in computer software or a video game. In role-playing videos, children may be able to choose a favorite character or switch characters as part of the play. Children use images from these media in their written narratives, their imaginative play, and their conversations with friends (Singer & Singer, 2008; Wohlwend, 2009).

Edward Carlile Portraits/Moment/Getty Images

Eric is solving a puzzle on his tablet while his sister looks on. She gives him suggestions about what to do, and they plan their strategy together. The computer environment can be a zone of proximal development when siblings or friends work together to advance their reasoning and problem-solving skills.

Given the extensive exposure to electronic media at young ages, additional research is needed to help clarify their impact. Concerns about the relationship of extensive media use to childhood obesity, possible interference with social communication and language development, and exposure to non-educational content deserve empirical study. The media environment may also contribute positively to the emergence of self-directed goal attainment, new capacities for managing multiple stimuli at once (multitasking), and new appreciation for music, art, poetry, and the natural environment through early exposure.

Friendship Groups

What can we expect about the nature of friendship in early school age? Friends clearly matter to young children. They make play exciting; they provide experiences of emotional closeness; and they create opportunities for new and interesting activities. The friendships of young children may not have the degree of loyalty, emotional intensity, and disclosure that are seen among older children and adolescents, but they certainly provide important experiences of companionship and affection (Dunn, 2004).

Friendships, by definition, are voluntary and reciprocal. Even young children choose who they want to have as their friends. You cannot make children befriend another child. Of the many children in a play group, preschool class, or kindergarten, some children like each other and want to spend time playing together; other children have no friends. The precise reasons that children are drawn to one another are not entirely understood.

For young children, friendships are likely based on proximity (living in the same neighborhood, or going to the same preschool), and the mutual enjoyment of activities. Friendships are maintained through acts of affection, sharing, and collaboration in fantasy or play that involves building or making things like block construction, or water table or sandbox play. Children may build snow forts together, play dolls or cars, create space adventures, or sleep over at one another's homes. By the age of 4 or 5, children who have stable friendships become skilled at coordinating their interactions with their friends, creating elaborate pretend games, and being willing to modify their play preferences so that both members in the friendship have a chance to enjoy the kinds of play they like best. Because they care about their friend, young children have opportunities to expand their sense of empathy. They show concern for their friends' troubles and offer help when they perceive that their friends need assistance (Vaughn, Colvin, Azria, Caya, & Krzysik, 2001).

Young children are sensitive to the norms for fairness and cooperation among friends and are more likely to be generous with their friends than with children they know who are not friends (Moore, 2009). The opportunity to form friendships benefits young children by enhancing their interpersonal sensitivity, social reasoning skills, and conflict resolution skills

(Volling, Youngblade, & Belsky, 1997). Having a good friend who has effective social and cognitive skills leads to more meaningful conversations between friends, less frustration and aggression, and more mutually satisfying companionship (Engle, McElwain, & Lasky, 2011; Salvas et al., 2011).

Conflicts Among Friends. Even though children appear to be drawn into the active world of peer friendships, it is an uneven, difficult, and often extremely frustrating terrain for many early-school-age children. Peer play is frequently disrupted by quarrels, tattling on others, and hard feelings about injustices. Friendships may be broken by taking away a toy, hitting, or name-calling.

Early-school-age children differ markedly in their social skills, language abilities, and the extent to which they understand or think about how another person is feeling or thinking. Moreover, some children have already achieved a fairly high level of self-control and are able to inhibit their angry impulses, while other children are still likely to take out their angry feelings on others by hitting, kicking, grabbing, and other aggressive acts.

Young children tend to evaluate situations on the basis of outcomes rather than intentions. Therefore, they are often harsh in assigning blame in the case of negative outcomes. For example, many 5- and 6-year-olds participate in play fighting. In a study of children's perceptions of play fighting, Italian and British children of ages 5, 8, and 11 were surveyed about the differences between real fighting and play fighting (Smith, Hunter, Carvalho, & Costabile, 1992). About half the children liked play fighting—a somewhat larger number of boys than girls. But about 80 percent thought there was a risk that play fighting could lead to a serious, real fight. This might happen if there was an accidental injury, if the play fighting got carried away into mean name-calling, or if, when one child accidentally hurt the other, the second child mistook the injury as purposeful and hurt the first child back. Five-year-olds said that if play fighting turned into real fighting, they would tell an adult. No matter whether the other child was a friend or not, they believed that such a transgression had to be handled with a serious intervention by a grown-up. The older children were more likely to forget about it, especially if the other person was a friend.

The quality of children's friendships and the extent to which their play is characterized by cooperative, positive interactions or conflicts and fighting depend on the social and cognitive maturity of the play companions. Some studies find that young children who have no or very few friends are also likely to be described by teachers as exhibiting more antisocial behaviors. They have difficulty controlling their anger and are likely to lash out at others (Engle, McElwain, & Lasky, 2011).

Some children seem especially preoccupied with violent fantasies, often fed by exposure to violent media, or as a result of exposure to power-assertive discipline and frequent angry interactions among adults at home. These children, who were described as "hard to manage," experience more conflicts in interactions with friends, are less willing to help other children, and are less effective at coordinating their play with others (Dunn & Hughes, 2001). Not surprising, when children find "best friends" who are similarly antisocial, it tends to accentuate their antisocial behavior, especially among boys (Eivers, Brendgen, Vitaro, & Borge, 2012).

Sex Segregation Among Friends. One of the most noticeable characteristics of young children's friendship groups is that they are likely to be segregated by sex. When boys and girls are free to choose play companions, they tend to choose others of their own sex. This pattern of same-sex social groupings among children is found not only in the United States, but also in most other cultures (Whiting & Edwards, 1992). In one longitudinal study, children at age 4½ were found playing with same-sex friends about three times more often than with opposite-sex friends. By age 6½, they were 11 times more likely to be playing with same-sex friends (Maccoby & Jacklin, 1987).

Sex segregation is promoted by cognitive, behavioral, and contextual/cultural factors (Martin, Fabes, Hanish, Leonard, & Dinella, 2011). Based on the earlier discussion of gender identification, it is clear that children expect others of the same sex to like similar activities, toys, and forms of play. Children form internal representations of what boys and girls are like as friends and playmates. These internal models guide the inferences they make as they engage in peer interaction (Markovits, Benenson, & Dolenszky, 2001). Thus, children are likely to seek others of the same sex because they believe these other children will have the same play preferences they have.

At the same time, boys and girls do appear to play differently, especially when in same-sex and mixed-sex groups. Thus, a preference for same-sex play groups may be fostered by feelings of comfort or discomfort as children accumulate play experiences. For instance, in the review of children's media play, researchers report a significant difference in boys' and girls' involvement in video game play. Seventeen percent of 5- to 8-year-old boys are daily video game players as compared to 5 percent of same age girls (Rideout, 2013). Some cultures discourage girls and boys from participating in the same types of play. For example, when children in a Brazilian tribal culture play family, the boys (husbands) go off to pretend to be hunting and fishing, returning with leaves that are then given to the girls (wives), who pretend to cook them and pass them out to the boys to eat (Gregor, 1977).

Environmental cues can enhance children's same-sex preferences. In an experimental study, some preschool teachers were asked to use gender-specific language when talking with the class while the control group teachers were asked to use gender-inclusive language. For example, in the experimental group a teacher might say: "Good morning girls and boys." In the control group a teacher might say: "Good morning children." After 2 weeks of this treatment, children's attitudes about gender stereotypes were measured and their preferences for play companions during free play were observed. Children in the experimental groups showed an increase in their agreement about gender stereotypes and a decrease in the amount of play with opposite sex children during free play (Hilliard & Liben, 2010).

The significance of the formation of same-sex social groups is that boys and girls grow up in distinct peer environments. The quality, tone, and content of social interactions differ depending on the sex of the child and the sex of their play companions (Fabes, Martin & Hanish, 2003; Sigelman & Holtz, 2013). The more children play with same-sex groups, the more they take on the gender-stereotypical attitudes and behaviors of their play companions (Maccoby, 1988, 1990; Martin, Fabes, & Hanish, 2011, 2014). Boys and girls use different strategies to achieve dominance or leadership in their groups. Boys are more likely to use physical assertiveness and direct demands; girls are more likely to use verbal persuasiveness and polite suggestions. The verbal exchanges in all-boy groups are apt to include frequent boasts, commands, interruptions, heckling, and generally playful teasing. Boys try to top one another's stories and to establish dominance through verbal threats. The interactions in all-girl groups, on the other hand, tend to include agreeing with and acknowledging the others' comments, listening carefully to one another's statements, and talking about things that bind the group together in a shared sentiment or experience. In mixed-sex groups, boys may be less controlling and dominating than they would be in all-boy groups, but this may still be more than girls find acceptable or comfortable. As a result, girls' negative views of boys are reinforced and their tendency to seek all-girl peer interactions increases.

In contemporary U.S. culture, children are not typically restricted from playing with opposite-sex friends. They actively construct their friendship groups and choose play companions with the help of parents and caregivers who may facilitate their play and coordinate with other families to arrange for playtime. Many young children form friendships with children of the opposite sex. In the case of Lee, she was best friends with her cousin, Bob. The two of them played endlessly, enjoying the same adventures and activities, getting into scrapes, and testing the limits of their initiative. These friendships may begin as early as infancy or toddlerhood between children who live in the same neighborhood or attend the same child care center. They are sustained by a compatibility of interests and play preferences and may survive the trend toward seeking same-sex friendships, even during early and middle childhood. There is evidence of a benefit to children who have more flexible preferences for play companions, including mixed-sex and same-sex play groups. Experiences with mixed-sex play groups are associated with exposure to a wider array of play activities and materials, and the emergence of positive emotional adjustment as children encounter the increasingly complex social environment of the mixed-sex classroom (DiDonato et al., 2012; Fabes, Hanish, & Martin, 2007).

However, the general preference for same-sex friendship groups is an important aspect of social development that is established during the early childhood years and continues into adolescence (Leaper & Bigler, 2011). Although a boy and a girl grow up in the same culture, the same neighborhood, and even the same family, the tendency to establish separate play and friendship groups fosters the development of distinctive gender-linked communication strategies and makes the achievement of mutual understanding between boys and girls difficult.

Groups and Dyads. In addition to the preference for same-sex friends, boys and girls tend to prefer to interact in groups of different sizes. Early-school-age girls seem to enjoy dyadic (two-person) interactions over larger groups, whereas boys seem to enjoy larger groups (Benenson, 1993; Markovits, Benenson, & Dolenszky, 2001). This is not to say that boys and girls cannot function effectively in both dyadic and larger peer group situations, but when given the choice, boys prefer the group and girls the dyad. These two configurations, the group and the dyad, provide different opportunities for intimacy, different needs to exercise dominance and control, and different problems in the coordination of action. They provide models for different forms of adult social relationships—the dyad being associated with intimacy between partners or in parent–child relationships, and the group being associated with sports teams, work groups, and families.

FURTHER REFLECTION: *Try to recall your favorite pastimes from the early-school-age years. How much influence did the media have on the kinds of games and play you enjoyed? What were some differences in the kinds of play you engaged in by yourself, with just one friend, and with a group of friends? How "gendered" or sex-segregated was your play?*

The Psychosocial Crisis: Initiative Versus Guilt

OBJECTIVE 5 Explain the psychosocial crisis of initiative versus guilt, the central process of identification, the prime adaptive ego quality of purpose, and the core pathology of inhibition.

As children positively resolve the psychosocial crisis of autonomy versus shame and doubt, they emerge from toddlerhood with a strong sense of themselves as unique individuals. During early school age, children shift their attention toward investigation of the external environment. They attempt to discover the same kind of stability, strength, and regularity in the external world that they have discovered in themselves.

Initiative

Initiative is an expression of agency and innovation—an outgrowth of early experiences of the self as a causal agent that continues to be demonstrated as children impose themselves and their ideas and questions onto their social world. You might think of imitation as a more conservative process in which a child copies behaviors that already exist in their family or community. In contrast, initiative suggests a creative expression of the child's imagination and curiosity (Nielsen, Tomaselli, Mushin, & Whiten, 2014). It is a manifestation of the *I*, the executive branch of the self that was discussed earlier in the section on self-concept. Initiative is the active, conceptual investigation of the world, in much the same sense that autonomy is the active, physical manipulation of it (Erikson, 1963). It can be recognized in a child's curiosity, inventiveness, exploratory behavior, and active coping strategies in the face of obstacles (Frese, 2001).

Children's curiosity about the order of the universe ranges from the physical to the metaphysical. They may ask questions about the color of the sky, the purpose of hair, the nature of God, the origin of babies, or the speed at which fingernails grow. They take things apart, explore the alleys and dark corners of their neighborhood, and invent toys and games out of odds and ends.

One expression of initiative is children's playful exploration of their own bodies and sometimes of their friends' bodies. It is not uncommon to find 5- and 6-year-olds intently involved in a game of doctor in which both doctor and patient have their pants off. Boys of this age may occasionally be observed in a game that is won by the child who can achieve the longest urine trajectory. Girls report occasions on which they have attempted to urinate from a standing position, attempting to imitate how a boy does. Both boys and girls engage in some form of masturbation. These behaviors are evidence of children's growing curiosity about and pleasure in their bodies and their physical functioning.

Children may express initiative while they are alone by attempting to discover how things work and by building or inventing novel devices.

> Donald kicked and knocked over an endless variety of things at hand. He put a block on top of a toy car, a leaf on top of that, then knocked the leaf off. Then he turned a truck over on its side, put a block on top of it, moved over to the car, stacked three blocks on top of it, and knocked the whole structure over. He took the car again, spanked it as if it were a doll, knocked it upside down, placed a leaf on top of it, then swept the leaf off. He played a little longer in this way, then ran out of the garage. (Murphy, 1962, p. 102)

In the home environment, many children express initiative by creating hiding places or private spaces. In these places, where children create a feeling of autonomy and control, they can impose their own form of creative play. These spaces, like under the table, in a closet, or behind the couch, can be used alone or with other play companions. Five-year-old Micah likes to use the space between the front door and the door to the house as a private play space. She fills the entry way with pillows and blankets, then she brings her little sister in with her and they pretend. It's definitely a "no grown ups" territory (Green, 2015).

Children may also express initiative in social play by asking questions, asserting their presence, taking leadership, and coordinating their ideas with their play companions. In play, children can express their agency by co-constructing fantasy situations, transforming materials to new uses, inventing roles, and establishing the rules of collaborative interactions. Pretend play is associated with enhanced creativity, divergent thinking, and emotional well-being, all features of a positive sense of initiative (Hoffmann & Russ, 2016; Stetsenko & Ho, 2015).

In one study of social competence, children described the strategies they used to enter a peer play group (Dodge, Pettit, McClaskey, & Brown, 1986). Two children were playing a game (they were referred to as the *hosts*), and a third child was asked to enter the room and try to initiate play with the others. The entry episode was videotaped and coded. The child who tried to initiate play and the two hosts were interviewed about the episode and asked to evaluate how successful the entry child had been. Three strategies for initiating interaction were judged to be effective and were associated with other evidence of social competence:

1. Children established common ground by giving meaningful information in response to questions.
2. Children engaged in a positive, friendly interchange with the others.
3. Children did not show evidence of negative, irritable behaviors.

The children who were least successful in initiating entry into the play "were disruptive, . . . made nagging, weak demands, . . . engaged in incoherent behaviors, or . . . disagreed with hosts without citing a rule or reason" (Dodge et al., 1986, p. 25).

The ability to engage with peers in a positive way is a key component of social competence. Children who are able to make their wishes and needs known, who can enter into peer activities easily and make appropriate contributions to group discussions and play are also more likely to become positively connected to their academic environment. The school is, after all, a social setting. In order for children to do well in school, they need to be able to establish and maintain positive peer relationships, a process that often requires initiative (Ladd, Herald-Brown, & Kochel, 2009; Oades-Sese, Esquivel, Kaliski, & Maniatis, 2011).

Children who experience a positive sense of initiative can apply this orientation to investigation of the physical as well as the social world. They innovate through the creation of magic potions mixed together with soap, perfume, pinecones, leaves, and other "powerful" ingredients. They create plays, stories, puppet shows, dances, and ceremonies. They dress up in costumes, entertain company by standing on their heads, engage in daring acts by hanging from tree limbs or walking on the tops of high ledges, and impose themselves in any and all curious and private discussions. They spend time trying to figure out ways to catch a glimpse of Santa Claus on Christmas Eve or the Tooth Fairy when she comes at night to collect her treasures. These are the years when a sense of initiative is associated with a naive, exuberant, entrepreneurial spirit and a desire to discover, direct, and dominate. All manner of investigation and inquiry is fair game.

The psychosocial crisis of initiative versus guilt is resolved positively when children develop the sense that an active, questioning investigation of the environment is informative and pleasurable. Inquiry is tempered by a respect for personal privacy and cultural values. However, the dominant state of mind is curiosity and experimentation. The child learns that, even though certain areas are off-limits, efforts to understand most aspects of the world are appropriate.

Guilt

Guilt is an emotion that accompanies the sense that one has been responsible for an unacceptable thought, fantasy, or action (Izard, 2004). It is a fundamental moral emotion usually accompanied by remorse and a desire to make reparation for real or imagined wrongdoing. It has the adaptive function of promoting social harmony because it disrupts or inhibits aggressive actions and leads people to ask for forgiveness or to compensate for wrongs they may have done. In comparison to *shame*, which often is accompanied by feelings of humiliation, anger, or resentment, guilt is typically tied to constructive efforts to repair the harm done to others (Bafunno & Camodeca, 2013; Tangney, 2001, 2012).

ungvar/Shutterstock.com

Sandy made her sister cry by calling her a bad name. Now she is in her room, thinking things over. For most children, occasional feelings of guilt lead to wanting to set things right and regain positive feelings with their family or friends.

Three theories offer different explanations for the dynamics that underlie feelings of guilt. The psychoanalytic perspective views guilt as an emotional reaction to one's unacceptable sexual and aggressive impulses. These impulses are especially threatening during the phallic stage, when hostility and feelings of sexuality toward one's parents become a focus of the child's wishes and must be repressed.

Research on empathy suggests that guilt may be awakened at a very early age through emotional arousal and sensitivity to another person's emotional distress. This view of guilt based on empathy is not defensive; it is closely linked to prosocial feelings and the basic emotional ties between infants and their caregivers.

The cognitive perspective suggests that guilt occurs when one fails to act in accord with one's own personal standards and beliefs. This view supposes a more advanced level of self-reflection and the ability to compare one's behaviors against personal standards.

Every culture imposes some limits on legitimate experimentation and investigation. Some questions may not be asked; some acts may not be performed. Adults' reactions determine whether the child learns to view specific behaviors, such as aggressiveness, sexual play, or masturbation, as wrong or acceptable. Children gradually internalize cultural prohibitions and learn to inhibit their curiosity in the taboo areas. One taboo shared by most cultures is the prohibition of incest. Most children learn that any behavior that suggests sexual intimacy between family members is absolutely forbidden. Even the thought of such a relationship comes to generate feelings of anxiety and guilt. The child's curiosity in other domains is limited to the extent that the family and the school impose restrictions on certain areas of inquiry or action. For example, children might be very curious to know what is happening in the teacher's lounge at school, but they are not allowed in there.

Guilt, like other negative poles of the psychosocial crises, can have an adaptive function. As children grow in their sense of empathy and ability to take responsibility for their actions, they are able to acknowledge when their actions or words may have caused harm to someone else. Normal levels of guilt have been associated with positive levels of prosocial behavior and high levels of empathy. Feelings of guilt generally lead to remorse and some attempt to set things right again, to restore the positive feelings in a relationship (Tangney, Malouf, Stuewig, & Mashek, 2012). In a longitudinal study, guilt-prone and shame-prone children were followed from elementary grades to later adolescence. At ages 18 to 21, the guilt-prone children were less likely to be involved in risky and illegal behaviors including less involvement with drugs and alcohol and less involvement with the criminal justice system (Stuewig et al., 2015).

Some children suffer from overwhelming guilt. They feel that each of their questions or doubts about the world is inappropriate. They may experience guilt about their own impulses and fantasies, even when they have taken no actions and no negative consequences have resulted. Moreover, these children begin to believe that their thoughts and actions are responsible for the misfortune or unhappiness of others. They do not seem to take any enjoyment in play, and their play is often characterized by negative or sad themes. Excessive guilt is one of the symptoms associated with early identification of depression in preschoolers (Luby, 2010).

Young children of depressed mothers express unusually high levels of distress, concern, rejection, and feelings of responsibility for others' unhappiness. Mothers who are consistently sad set an example of blaming themselves for most of the bad things that happen. Depressed mothers are likely to withdraw love when the child has misbehaved—a discipline technique associated with high levels of guilt and anxiety in children. In this environment, children learn to restrict new behaviors out of fear that they may cause harm or unhappiness to someone else (Rakow et al., 2011; Zahn-Waxler & Van Hulle, 2012). Children who resolve the crisis of initiative versus guilt in the direction of guilt are left to rely almost totally on their parents or other authorities for directions on how to operate in the world.

The psychosocial crisis of initiative versus guilt highlights the close tie between intellectual curiosity and emotional development. During this stage, parents and the school transmit the cultural attitudes toward experimentation, curiosity, and investigation. They also make demands that direct the child's curiosity away from familial, subgroup, and cultural areas of taboo. Children are expected to develop the ability to control their own questions and behavior. While violations may bring disapproval and punishment, successful self-control may attract no notice whatsoever. Children must develop a strong internal moral code that will help them avoid discipline. They must also develop the ability to reward themselves for correct behavior. The more areas of restriction that are imposed on children's thinking, the more difficult it is for children to distinguish between legitimate and inappropriate areas of investigation. One way that children have of coping with this problem is to develop a rigid moral code that restricts many aspects of thought and action.

FURTHER REFLECTION: *Describe the behaviors that you would expect to observe in a child who had a strong sense of initiative or a strong sense of guilt. Speculate about how the sense of initiative is built on the earlier crises of trust versus mistrust and autonomy versus shame and doubt. Explain why guilt is more likely to be linked to reparation than shame.*

The Central Process: Identification

Identification is the central process in the resolution of the conflict between initiative and guilt. We introduced the concept of identification in discussions of gender identity, moral development, and self-concept. In each of these tasks, the sense of self is clarified in the context of interactions with significant others. As a result of identification, children internalize salient cultural values. Children actively strive to enhance their self-concepts by incorporating into their own behavior some of the valued characteristics of their parents. Through a variety of processes, including watching the behavior of others, imitating others, engaging in activity where others are watching, and participating in play, conversation, and problem solving with others, children form an internal representation of the self that is coordinated with the representation of the other (Decety & Chaminade, 2003).

Four different theories suggest motives for identification (see Table 7.5). The *fear of loss of love* is founded on a child's initial realization of dependence on the parents. A child behaves like a parent in order to ensure a continued positive relationship. Eventually, the child incorporates aspects of the loved one's personality into the self-concept. The child can then feel close to the loved person even when they are not physically together (Jacobson, 1964).

Identification with the aggressor is aroused when children experience some fear of their parents. In order to protect themselves from harm, they perform behaviors that are similar to those they fear. Children identify even with parents who are extremely brutal. Because most of the behaviors that these children incorporate are aggressive, they often tend to be aggressive toward others. This kind of identification may give children a magical feeling of power and decrease the parents' tendency to mistreat them. Parents who see great similarity between themselves and their children are less likely to threaten or harm them (Freud, 1936).

A third motive for identification is the *need for status and power* (Bandura, 1977, 1986). Children are more likely to imitate the behavior of a model who controls resources than they are the behavior of a model who is rewarded. The imitative behavior is motivated by a vicarious feeling of power experienced when they behave in the same way as the powerful model. Within a family, children are likely to have personality characteristics similar to those of the more dominant parent.

A fourth motive for identification results from the *children's need to increase the perceived similarity with their parents* (Kagan, 1958). Children attribute a number of valued characteristics to their parents, including physical size, good looks, special competencies, power, success, and respect. Children more readily share these positive attributes when they perceive a similarity between themselves and their parents. They experience this sense of similarity in three principal ways: by (1) perceiving actual physical and psychological similarities, (2) adopting parental behaviors, and (3) being told about similarities by others. Increasing perceptions of similarity promote stronger identifications.

These four motives apply to the process of identification at all ages and regardless of the sex of the identifier or the model. For a particular child, one of these motives may dominate, but all four motives are involved in the process. Parental identification allows children to feel that their parents are with them even when they are not physically present. This feeling of connection with parents provides an underlying sense of security for children in a wide variety of situations.

Viewed from another perspective, identification allows children a growing sense of independence from their parents (Jacobson, 1964). Children who know how their parents would respond in a given situation no longer need the parents' physical presence to direct their behavior. Children who can praise or punish themselves for their actions are less dependent on their parents to perform these functions.

Parental identification affects children's development in two different ways. On the one hand, the closeness with parents provides the basis for the incorporation of parental sanctions and prohibitions. Once children have integrated these guidelines for behavior, they are bound to feel guilty whenever they anticipate abandoning them. On the other hand, the security that results from strong parental identification allows children increased freedom when they are away from their parents. The child whose parental identification is strong is more likely to engage the environment, take risks, and initiate actions.

An important outcome of early-school-age identification is the formation of an ideal self-image, sometimes referred to as the **ego ideal** (Freud, 1909/1955; Sandler, Holder, & Meers, 1963). The superego not only punishes misdeeds but also rewards actions that bring children closer to their ideal self-image. The ideal self is a complex view of the self as it may be in the future, including skills, profession, values, and personal relationships. It is a fantasy, a goal that is unlikely to be attained even in adulthood. Nonetheless, the discrepancy between the real self and the ideal self is a strong motivator. As children strive to achieve their ideal, they attempt new activities, set goals that strain the limits of their abilities, take risks, and resist temptations that might interfere with their desired goals.

The ego ideal is more unrealistic during early school age than at later stages. Young children fantasize anything they wish about themselves in the future. The ideal self may include the strength of Superman, the courage of Harriet Tubman, and the intellectual

Table 7.5 Four Motives for Parental Identification

Motive	Definition
Fear of loss of love	A child behaves like a parent in order to ensure a continued positive love relationship.
Identification with the aggressor	A child behaves like a parent in order to protect himself or herself from the parent's anger.
Identification to satisfy needs for power	A child behaves like a parent in order to achieve a vicarious sense of the power associated with the parent.
Identification to increase perceived similarity	A child behaves like a parent to increase a perceived similarity to the parent and thereby to share in the parent's positive attributes.

Identification is the central process through which children develop an ego ideal. A dad and his son talk about what it means to be a good person as they look out over the water.

brilliance of Einstein. The lack of realistic constraints on the ego ideal allows children to imagine the possibility of attaining human qualities that may always be beyond their reach. As people mature, they need to modify their ego ideal so that it remains inspiring, yet includes emerging insights about oneself, one's groups, and society. People who find it difficult to modify their ideal self-image from its childhood origins may become vulnerable to personal frustrations and psychological despair because they are unable to be what they wish. Many 6-year-old children may wish to become president of the United States. This fantasy is exciting and, for some, ennobling. However, few people actually achieve this position. By the time one reaches early adulthood, it is important to have developed an ego ideal that is closer to what is actually attainable.

The crisis of initiative versus guilt captures the child's need to question existing norms and the emerging feelings of moral concern when these norms are violated. This crisis does not focus specifically on intellectual development; however, one may assume that the level of questioning that takes place during this stage is possible only because of an increase in cognitive complexity. The process of positive parental identification promotes the incorporation of cultural norms and strengthens the child's sense of competence. Socialization during this stage may either foster a creative openness or an anxious dread of novelty.

The Prime Adaptive Ego Quality and the Core Pathology

As a result of efforts to resolve the crisis of initiative versus guilt, children emerge from the period of early school age with the benefit of the prime adaptive ego quality of purpose or the core pathology of inhibition. These predispositions suggest an orientation that leaves a child with coping resources that will support directed, action-oriented problem solving or a more passive, self-protective approach to stress in which the child is more likely to allow others to guide the course of behavior.

Purpose

Purpose is thought or behavior with direction and meaning. "Purposefulness is the courage playfully to imagine and energetically to pursue valued goals," noted Erikson (1978, p. 29). Purpose is linked to personal aspirations. It is a cognitively more complex extension of the will gained in toddlerhood, in that it combines a sense of agency with a plan and a belief in one's ability to make something happen. In contrast to the toddler who exercises the will through the mere delight in action, the early-school-age child imposes intention and goals on action. This is the difference, for example, between running around the yard, laughing and shouting—typical behavior for toddlers—and saying to a friend, "Let's play tag," which is more likely for early-school-age children. Toddlers may enjoy stacking blocks and knocking them down, or splashing in water; in contrast early-school-age children want to turn materials and toys into a story or a project. Their actions are going in a direction; their play has a plan. Behind the process of planning is a complex sense of the situation, creating a goal, devising strategies to achieve it, implementing these strategies in action, and monitoring success in realizing the goal (Deci & Ryan, 2000). The sense of purpose, expressed in planning and enacting plans, reflects a significant expansion of the ego into the realm of the present and the future.

A sense of purpose suggests that the action has meaning and that the person initiating it has meaning. Purposeful behavior suggests that the child is aware of something meaningful in the world outside the self that needs attention, and a sense of confidence in the ability to contribute to that goal (Damon, 2014). Purpose can be nurtured by involving children in meaningful tasks that contribute to the well-being of the family; supporting children as they set some of their own goals and encouraging them to figure out how to achieve them; and by giving children opportunities to observe family members, friends, or relatives who are pursuing meaningful goals that they believe in. Ricky comes home from preschool and says, "Let's take all our plastic bags to the recycle bin at the grocery so we can save the planet." This suggestion reflects Ricky's ability to state a goal-directed plan that addresses a meaningful concern and a sense of confidence about introducing his idea into the ongoing activities of the family.

The sense of purpose is a key resource throughout life. The assumption introduced in chapter 1 that people contribute to their development relies on the emergence and elaboration of a sense of purpose. At later ages, especially in later adulthood and

Coach Carl is guiding Billy to overcome his doubts and to keep trying to make a basket. Goal-directed play becomes increasingly important in early school age and requires a sense of purpose. A few successes will make a big difference in his confidence.

elderhood, many of the more structured and well-defined life roles are relinquished. In their place, adults need to invent and impose a new sense of purpose that provides satisfaction and meaning to daily life (Penick, 2004).

Inhibition

As a core pathology, **inhibition** refers to a self-conscious restraint or suppression of thoughts and behavior. As we discussed in chapter 5, inhibition has temperamental origins. As a core pathology, however, inhibition becomes problematic when parents or caregivers use high levels of love withdrawal and guilt-inducing interactions with their children. These kinds of interactions suggest that the parent's love, affection, and approval are based on the condition that the child must match certain specific parental standards. In order to adapt in this kind of environment and avoid risking loss of love, the child becomes unsure and restrained in action. In contrast to the sense of confidence and agency implied in the notion of purpose, a child who is inhibited does not want to take the risks associated with imposing a plan or suggesting a direction for fear that suggestions will result in parental or peer disapproval.

As with other core pathologies, some degree of inhibition is necessary and adaptive. In chapter 6, we addressed the topic of self-control, pointing out the important adaptive value for young children of being able to resist temptations, regulate their emotions, and restrict behaviors when the situation requires it. As the executive functions mature, early-school-age children are expected to demonstrate an increasingly high level of behavioral inhibition especially in school and family settings where patience and delay of gratification are often required. Deficits in inhibitory control during early childhood are linked to later problems with externalizing behaviors as well as anxiety and depression (Kertz, Belden, Tillman, & Luby, 2015). However, as a core pathology, extreme inhibition can be observed in children who are intensely timid, overly cautious, and socially anxious.

Inhibited children are likely to emerge as shy, withdrawn, and often lonely during the subsequent period of middle childhood. Shyness is associated with self-consciousness and a fear of negative evaluation that can inhibit participation in desired activities and cause withdrawal from social situations. Without some form of social intervention, shy children may become increasingly withdrawn, not knowing how to impose their ideas into the ongoing activities of the group, and not experiencing the confidence-building effects of making suggestions and having them accepted. Consequently, their inhibition produces new deficits in social skill development (Henderson, Gilbert, & Zimbardo, 2014).

FURTHER REFLECTION: *What does a sense of purpose look like in early-school-age children? How might a sense of purpose contribute to a child's ability to cope with difficult stressful situations? What advice might you offer to parents about how to foster the sense of purpose and minimize inhibition as children make the transition to kindergarten?*

Applied Topic School Readiness

OBJECTIVE 6 Define the concept of school readiness, and analyze its relation to the developmental tasks of early school age. Summarize the obstacles that may prevent children from being able to adapt and learn in the school environment.

The first years of schooling are critical in setting the long-term pathway for school achievement. A federal priority for improving the quality and access to educational opportunities in early childhood began with the establishment of the Head Start programs in the 1960s, continued with the emphasis on preparing young children to reach kindergarten "ready to learn" in the 1980s, and is an ongoing priority to ensure that children are prepared for success by their entry in kindergarten. In his State of the Union speech in 2013, President Obama proposed extending federal funds to expand high-quality public preschool to reach all low- and moderate-income 4-year olds (The Education Innovator, 2009; White House, 2013). This goal, which seems positive and appropriate on the face of it, has resulted in important dialogue about what is meant by **school readiness**, how to measure it, what obstacles stand in its way, and who should be responsible for achieving it (Wesley & Buysse, 2003).

What Do We Mean by Readiness?

The concept of readiness is a familiar idea in the study of development. Typically, the term is used to refer to a time when a child's physical, cognitive, social, and emotional maturation are at a level to undertake new learning or to engage in a more complex, demanding type of activity or relationship. It is sometimes referred to as a critical or sensitive period or a teachable moment. The idea of a *sensitive period* was identified in chapter 5 in relation to attachment relationships, in chapter 6 in relation to language use and toilet training, and in this chapter in relation to gender-role identification. Vygotsky's concept of a *zone of proximal development* is another way of conceptualizing readiness; it is the next higher level of performance one can achieve with the help of more competent mentors, teachers, and peers.

When thinking about the goal that all children should come to school ready to learn, the concept of readiness becomes somewhat more complicated. Does it refer to readiness to learn or readiness to be successful in school? One might argue that all children—except perhaps those with severe neurological damage—are both ready and eager to learn. However, not all children have the combined physical, cognitive, emotional, and social skills that allow them to adapt to the demands of the kindergarten environment or to succeed at the academic challenges of its curriculum without support (Bowman, Donovan, & Burns, 2000; Early, Pianta, Taylor, & Cox, 2001).

Measuring Kindergarten Readiness

In the past, kindergarten readiness was established largely by chronological age. School districts typically established a birthday cutoff. For example, if a child was 5 by December 1 of a given year, the child could start kindergarten in September of that year. Those who missed the December 1 date had to wait until the following year. In the 1980s, concern about the quality of education in the United States led to an upgrading of the elementary school curriculum. As part of this school reform, academic demands for school performance were raised, and children were exposed to a more challenging curriculum in earlier grades. Many skills that had been introduced in first grade are now part of the kindergarten curriculum, and more children are having trouble meeting the expectations for school performance. As they enter kindergarten, children are expected to have some experience with printed letters and sound recognition along with beginning writing skills. They are also expected to have a repertoire of behavioral and emotional skills that support attention, persistence, and cooperative social interactions with teachers and peers (Federal Interagency Forum on Child and Family Statistics, 2013; Hatcher, Nuner, & Paulsel, 2012).

In efforts to prevent early school failure, many states began to administer school readiness tests. However, there is no agreement or universal acceptance of a measure of kindergarten readiness. Some educators dispute whether any test given to 5-year-olds can accurately predict a child's ability to learn in the school environment (Pyle, 2002). The American Academy of Pediatrics suggests that these tests are more often used to keep some children out of kindergarten rather than to identify areas where children may need additional support in order to succeed (High, 2008).

According to the National Association for the Education of Young Children (NAEYC), there are four appropriate uses for assessment: to support instruction, to identify those with special needs, for program evaluation, and for high stakes accountability. "Use of kindergarten readiness assessments as a means of screening children into or out of kindergarten is **inconsistent** [emphasis added] with generally accepted best practices and NAEYC's formal position on the inappropriate use of kindergarten assessments to keep an age-eligible child from enrolling" (Snow, 2011). When it comes to school readiness, norm referenced assessment techniques typically fail to include the role of motivation, temperament, and social and cultural factors that may influence the various strategies and processes that young children use for learning (High, 2008).

Most 5-year-olds do not read or write, so mass testing is not feasible. Any approach to measuring kindergarten readiness must involve one-on-one evaluation. Many early childhood educators emphasize that cognitive skills in reading, mathematics, and general knowledge are not enough to understand the child's readiness for school. School readiness is a comprehensive construct which draws on many of the developmental tasks reviewed in the chapter. Physical development and motor coordination, attention and executive control, social skills, communication skills, and a child's enthusiasm for learning all play a part in how well a child will adapt to the school environment (Grimm, Steele, Mashburn, Burchinal, & Pianta, 2010).

Increasing attention is being given to social and emotional resources that support children's learning and ability to cope with the demands of the school environment (DeAngelis, 2010). The way a child approaches learning, such as task persistence, attentiveness, and organization; a child's capacity for self-control and behavioral regulation; and a child's interpersonal skills, such as getting along with others and being able to express one's feelings and ideas in a positive way are all aspects of social and emotional competence that contribute to school success (Galindo & Fuller, 2010; Ponitz, McClelland, Matthews, & Morrison, 2009).

Bill Aron/PhotoEdit

These children are learning a fundamental skill for success in school: walking in line.

Given the lack of an objective, accepted measure, or screening test, what do parents and teachers think are essential markers of school readiness? How can a parent judge if a child is ready or should wait a year before beginning kindergarten? Advice about kindergarten readiness is diverse. States have issued their own readiness checklists. Online sources reflect at least three different perspectives: (1) recommendations for preschool educators, especially NAEYC, about how to assess the curriculum in order to prepare young children to be successful in the transition to kindergarten; (2) recommendations from teachers, especially the American Federation of Teachers, about how to evaluate kindergarten readiness; and (3) recommendations for parents, which come from many sources, both professional and informal. For example, the Urban Child Institute (2016) offers this advice to parents: "There are four key dimensions of readiness—language and literacy, thinking skills, self-control, and self-confidence." On their website they list the following skills that teachers and child development experts suggest for a child to be successful in the transition to kindergarten:

- Know her first and last name and her parents' first and last names.
- Recognize letters (both lowercase and uppercase) and numbers (up to 10).
- Communicate wants and needs (like hunger, pain, happiness) through words.
- Know basic colors and shapes.
- Use the bathroom and wash her hands all by herself.
- Solve problems without hitting, biting, or yelling.
- Follow instructions from teachers and parents.
- Be comfortable being apart from her parents during the school day.
- Sit quietly for short periods of time.
- Be curious and interested in activities like story and art time.

In an attempt to provide a systematic picture of what kindergartners are able to do at the start of school, the U.S. Department of Education initiated the Early Childhood Longitudinal Study, Kindergarten Class of 1998–1999 (Zill & West, 2000). A new cohort of kindergarteners was studied in the 2010–2011 school year. This national sample of more than 18,000 kindergartners from 970 schools will be followed through fifth grade (Federal Interagency Forum on Child and Family Statistics, 2013). In addition to one-on-one assessment of children, information was gathered from parents, teachers, special education teachers, school administrators, and child care providers. Reports from the first data collection focus on children's reading, math, and science knowledge; their body-mass index; and their approach to learning. This last category included a number of behaviors that reflect executive function, social competence, positive outlook, and emotional regulation: "the child's ability to keep belongings organized, pay attention well, persist in completing tasks, show eagerness to learn new things, work independently, adapt easily to changes in routine, and follow classroom rules." The expectation is that these assessments will provide norms for what most children can do when they come to kindergarten and allow consideration of how these early abilities predict subsequent school success (Federal Interagency Forum on Child and Family Statistics, 2013; Mulligan, McCarroll, Flanagan, & Potter, 2015). A report of how kindergartners performed on each of the areas assessed can be found in *America's Children: Key National Indicators of Well-being, 2013, Special Feature, The Kindergarten Year* (Federal Interagency Forum on Child and Family Statistics, 2013).

Risk Factors for School Readiness

Most children are excited about going to kindergarten and want to do well. However, certain demographic characteristics are linked to school readiness skills and approaches to learning in kindergarten. In the fall of the year when children first started kindergarten, the following differences in approaches to learning were observed:

Boys were rated lower than girls.

Younger children were rated lower than the older children.

Children whose parents had less than a high school education were rated lower than children whose parents had more formal education.

Children whose families were below 100 percent of the poverty level were rated lower than children from families at 200 percent of the poverty level or higher.

FIGURE 7.2 ▶ shows the differences in approaches to learning for boys and girls, and for children from three different levels of family income measured in the fall and again in the spring of their kindergarten year. All children showed some gains in approaches to learning from fall to spring. However, after a year of kindergarten, differences between the groups were still evident.

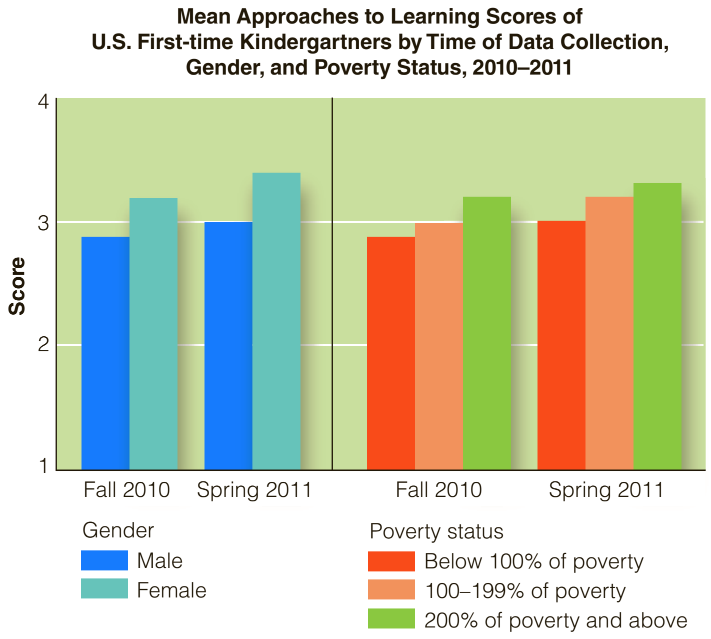

FIGURE 7.2 ▶ KINDERGARTENERS' APPROACHES TO LEARNING BY GENDER AND POVERTY STATUS, FALL 2010 AND SPRING 2011

NOTE: Approaches to learning behaviors include children's ability to keep belongings organized, pay attention well, persist in completing tasks, show eagerness to learn new things, work independently, adapt easily to changes in routine, and follow classroom rules. Higher scores demonstrate more positive approaches to learning. Approaches to learning scores are derived from teacher ratings. Estimates pertain to a sample of children who were enrolled in kindergarten for the first time in the 2010–2011 school year. Potential approaches to learning scores range from 1 to 4.

SOURCE: U.S. Department of Education, National Center for Education Statistics, Early Childhood Longitudinal Study, Kindergarten Class of 2010–2011 (ECLS-K:2011) Restricted-Use Kindergarten Data File.

In the analysis of kindergartners from the earlier 1998–1999 cohort, four factors were identified as placing children at risk for poor early school experience: parents who had not graduated from high school, low income or welfare dependence, single-parent families, and families where a language other than English was the primary language spoken at home (Zill & West, 2000). Forty-six percent of kindergartners had one or more of these risk factors. Having one or more risk factors was associated with lower scores in reading and mathematics and poorer health. Children with multiple risk factors were more likely to be described by teachers as having difficulty paying attention or persisting in the completion of a task and were more likely to be described as sometimes or never eager to learn, in contrast to children with no risk factors.

Certain microsystem environments can undermine a child's cognitive, emotional, social, and physical readiness for school. Poverty, stress, and disorganization can all impact the quality of parenting and the nature of the early learning environment (Son & Peterson, 2016). Harsh, controlling parenting has been linked to poor executive functioning, withdrawal, and an increased risk of externalizing problems. Household disorganization and instability, especially frequent moving from one residence to another, changes in the presence or absence of adults in the home, particularly the mother and father figures, the total number of people in the home, and the continuous ambient noise in the home are all associated with less optimal parenting behaviors. Children in these family environments show evidence of poorer executive functioning and problems in behavioral regulation from ages 3 to 5 (Vernon-Feagans et al., 2016).

Despite the essential role of the family and home environment, quality early childhood programs can make a real contribution in reducing risk and supporting kindergarten readiness. For example, an enhanced, evidence-based curriculum that was incorporated into a number of Head Start centers was found to have long-lasting contributions to children's social-emotional functioning including improved social competence, less aggressive-oppositional behavior, more learning engagement, fewer attention problems, greater teacher–student closeness, and fewer experiences with peer rejection (Nix et al., 2016). Early childhood programs can also form effective partnerships with parents to alter the home environment for children. For example, within Head Start programs, those that have a targeted parent-involvement emphasis find evidence of more cognitive stimulation activities at home and less use of harsh, controlling parenting, both of which are tied to children's academic and behavioral skills (Ansari & Gershoff, 2016).

Who Is Responsible for Meeting the Goal for School Readiness?

School readiness and school success are products of the interaction of the individual child, the child's family environment and early learning experiences, the particular school that the child attends, and the larger community that does or does not invest in the support of teachers and school (U.S. Department of Health and Human Services, 2011). In establishing a national priority for children to start school ready to learn and prepared to succeed, we are faced with this question: "Whose responsibility is it to meet this goal?" Do we need to provide more support to families to provide the early experiences that will foster health, confidence, motivation, and cognitive and social development during the first 4 years of life? Do we need to place more responsibility on schools to work with children where they are by providing the environment, services, curriculum, and methods of instruction that will facilitate learning for an increasingly diverse group of students? Do we need to place more responsibility on local, state, and federal government to sustain and expand programs such as Head Start, so that more children can participate in early educational experiences that help offset the negative effects of poverty?

Since school attendance is not required by law before the age of 6, kindergarten is optional. A child's family has the primary role in deciding whether or not a child is ready to start kindergarten. Some parents worry or wonder if their child is ready. Their decision is based on their own day-to-day observations, information they have received from the child's preschool/Head Start program, guidelines provided by the elementary school where the child might begin kindergarten, advice from family and friends, and/or from books and websites about school readiness. What if parents decide the child is not ready? A few strategies are possible: (1) Delay entry. Evidence suggests that children who are older do better in kindergarten than those who have not yet turned five when school starts. (2) Meet with the school counselor and the kindergarten teachers at the elementary school, describe your observations and find out if these concerns would result in significant difficulties in school adjustment. Many schools have a pre-kindergarten program for children who are not old enough or not quite ready to approach the kindergarten environment. (3) Have the child evaluated by a pediatrician or assessed by a psychologist to determine whether the child has special needs that might require additional accommodations. See the **Human Development and Diversity** box for a discussion of how to support school readiness for children with disabilities.

The child's chances of success in school can be improved if *all* interacting systems support one another and keep the goal of academic success for the widest range of students in focus. Schools need to be attuned to the characteristics of their incoming kindergartners. Professionals need to identify the physical, cognitive, social, and motivational factors that support school success and find ways to support development in those domains during infancy and early childhood. Parents need to foster a home environment that supports their child's interest and motivation for learning as well as providing opportunities for the acquisition of specific school-related competences. Educators and parents must become partners for the optimal development of children, identifying those children who are at risk for school failure and making plans for integrated, multiyear, multiservice programs to support their success.

FURTHER REFLECTION: *Analyze the biological, psychological, and societal factors that contribute to school readiness. Discuss ways that a caring community might support school success for a diverse group of learners in the transition to kindergarten.*

HUMAN DEVELOPMENT AND DIVERSITY

Supporting School Readiness for Young Children with Disabilities

About 4 percent of young children ages 3 through 5 have been identified as having a disability described as (1) developmental delay; (2) difficulty walking, running, or playing; or (3) both of these (Brault, 2011). By definition, children with a developmental delay are performing at or below the 50th percentile of their age-mates in one or more domains, including motor skills, speech and language, social and emotional competence, and learning and memory (Siegel, 1996).

In the national longitudinal study of the kindergarten class of 1998 to 1999, about 10 percent of the children were identified by their parents as having a developmental difficulty. For that study, a child with a developmental difficulty was defined as one whose parents noted a problem by first grade and obtained “a diagnosis from a professional for problems related to attention, activity, communication, hearing, or sight that could not be corrected with eyeglasses” (Malone, West, Flanagan, & Park, 2006).

The term **disability** can refer to a wide variety of possible functional challenges. The two most common impairments are speech and language delays (55 percent of those receiving services) and developmental delays (25 percent of those receiving services). In the study of American kindergartners, parents reported that “substantial minorities of children are already experiencing risks for developmental difficulties, with one in five being described as overly active, one in six having problems concentrating for sustained periods, and one in nine not articulating words clearly or fluently” (Zill & West, 2000).

Preschool and kindergarten programs that include children with disabilities face a significant task—to ensure that the inclusion benefits the child both socially and academically. Many children with disabilities are mainstreamed in a classroom without any provision for encouraging social interaction with the other children. One of the major concerns facing teachers is the ability to promote positive social skills, including appropriate levels of assertiveness, self-control, and cooperation among students of varying abilities (U.S. Department of Education, 2002). The school setting makes specific demands on children to function in more constrained, regulated ways than might be required at home. Some children benefit from the routine and predictability of the school setting, whereas others have difficulty regulating their behavior to comply with teacher and peer expectations.

Effective **inclusion** requires strategies for promoting contact between students with and without disabilities and creating an accepting social climate among students. Interventions must be tailored to address the unique areas of deficit. A child with autism, for example, may need to be taught how to imitate a model and may have difficulty cooperating with peers but might be able to play successfully with puzzles or listen to the teacher read a story. A child with moderate neurological deficits may have difficulty with tasks that require fast reaction time, such as competitive games among students, but could perform well if speed of response is not a concern. Children with speech and language difficulties may find it difficult to express themselves or to engage in conversation with peers. As a result, they may withdraw from social interactions. Teachers need to find ways to build on each child’s level of performance so the child is not stigmatized for a disability and continues to make progress toward an appropriate academic standard.

Critical Thinking Questions

1. Investigate the kinds of accommodations that schools make for children who have been identified as having serious, moderate, and mild disabilities. You may want to contact someone at a local elementary school or the school you attended to find out what they are required to provide. How might this have changed since you were in elementary school?
2. Evaluate the advantages and disadvantages of mainstreaming early-school-age children as compared to placing these children in special education classes.
3. Given what you know about the early-school-age period, summarize some of the challenges to effective inclusion. How might a course in human development help teachers meet these challenges?
4. Request permission to attend an IEP evaluation team meeting. How do the professionals from various disciplines approach the challenges for creating a supportive plan?

CHAPTER SUMMARY

Early school age marks the beginning of work on developmental tasks that will persist well into adulthood. The four tasks of early school age are closely interrelated.

OBJECTIVE 1 Describe the process of gender identification during early school age and explain its importance for the way a child interprets experiences.

The complex process of gender identification has cognitive, affective, physical, and interpersonal elements. Gender identification includes: (1) understanding the concept of gender, (2) learning gender-role standards and stereotypes, (3) identifying with parents, and (4) forming a gender preference. As young children clarify the content of their gender identification, they create a set of beliefs about the self, including their self-worth, relationships with other children, and the kinds of activities and interests that are appropriate for them, not only in the present but also in the future. The gender identification of the early-school-age child will be revised and reintegrated as it becomes a core element of personal identity in adolescence.

OBJECTIVE 2 Summarize the process of early moral development, drawing from theories and research to explain how knowledge, emotion, and action combine to produce internalized morality.

Early moral development involves the integration of three components: knowledge of the moral standards, experiences of moral emotions, and the willingness and ability to take moral actions. The development of conscience, with its capacity to reward and punish, brings an internalization of moral standards. Five theories are discussed that offer different views on the process of internalization: learning theories, cognitive developmental theory, psychoanalytic and object relations theories, and evolutionary theory. Research on empathy, caring, and perspective taking add insights into the processes through which morality matures in early school age. Two significant environmental forces, parental discipline and exposure to models and messages in the media, shape a child's moral outlook. Moral development is accompanied by a heightened sensitivity to violating basic cultural standards, many of which relate to interpersonal behavior, especially toward adults and peers. The child's experiences with transgressions, guilt, or praise for prosocial behavior have implications for the elaboration of the self-theory and particularly for the establishment of self-esteem.

OBJECTIVE 3 Analyze changes in the self-theory, with special focus on the theory of mind and self-esteem during the early-school-age years.

The self-concept can be viewed as a theory that links the child's understanding of the nature of the world, the nature of the self, and the meaning of interactions between the two. Various neural structures are actively involved in processing and integrating information to support the self-concept. Two faces of the self—the I and the Me—contribute to self-understanding. One is the originator of thoughts and actions; the other is the self as object as perceived by oneself and others. The self-concept becomes increasingly complex as gains from infancy and toddlerhood undergo developmental changes, brought about in part by changing neural development, new cognitive capacities, and changing societal expectations. Although the self-theory is continuously revised with entry into new roles and the emergence of new cognitive capacities, the establishment of a positive sense of worth in early school age brings an important tone of optimism as the child faces new challenges. Competence and social acceptance are the essential antecedents of self-esteem.

OBJECTIVE 4 Describe the features of peer play, including group games, media play, and friendship in the early-school-age years.

Play takes on new complexities including games with rules and multiple roles, exposure to diverse forms of media, and participation in friendship relationships. Children spend an average of 2 hours a day with some type of screen media, making media an increasingly dominant feature of the family system and an important play companion even at this young age. The type and content of media exposure differs by family income. Increased involvement with peers brings about an appreciation of others' perspectives, social acceptance, and delight in the intimacy of friends as well as new experiences with conflict and conflict resolution. Children's sense of initiative and purpose are reflected in the ways they actively create their social environment through their choice of games, media entertainment, and friends. The social worlds of boys and girls become notably distinct as gender preferences are expressed in different patterns of play and play companions.

OBJECTIVE 5 Explain the psychosocial crisis of initiative versus guilt, the central process of identification, the prime adaptive ego quality of purpose, and the core pathology of inhibition.

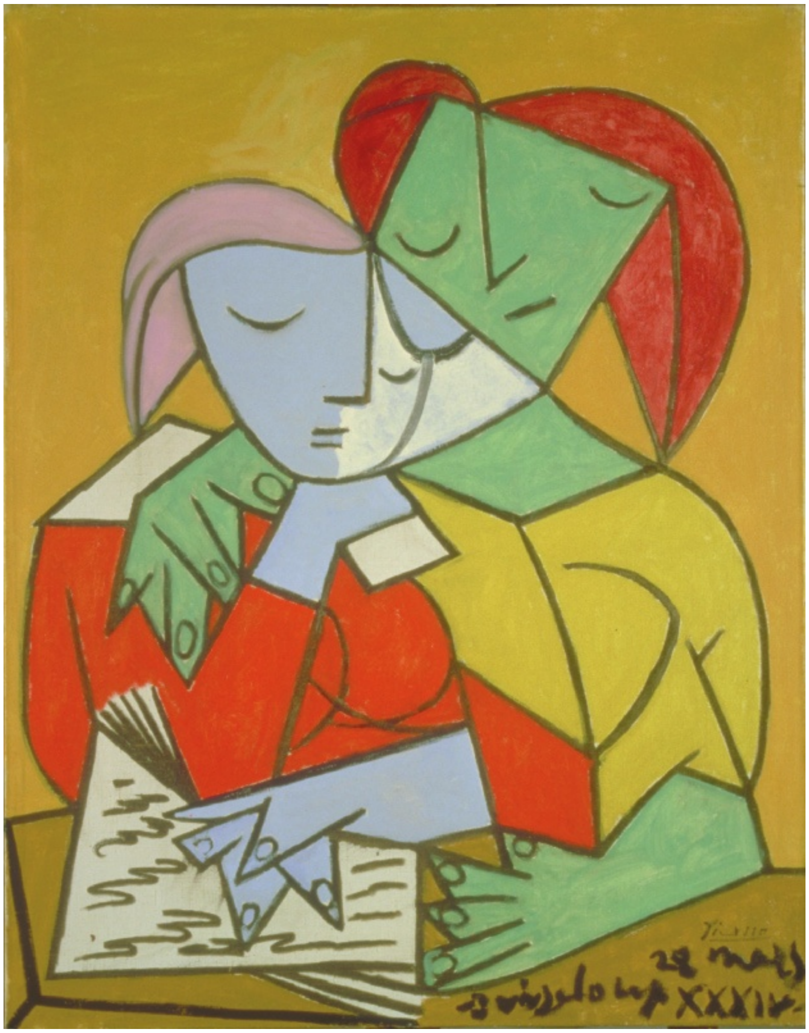
The psychosocial crisis of initiative versus guilt has direct implications for such essential personality characteristics as self-esteem, creativity, curiosity, and risk taking. The child who resolves this crisis positively will be fortified with an active, exploratory approach to the environment. Guilt plays an important role in orienting children toward the implications of their actions for others. In moderation, guilt is an essential ingredient in preserving social bonds. In the extreme, however, guilt restricts creative thought and limits action. As a result of identification, children internalize salient cultural values. Four different theories suggest motives for identification: fear of loss of love, identification with the aggressor, need for status and power, and the need to increase perceived similarity with one's parent. The prime adaptive ego quality of purpose emerges as children become aware of something meaningful in the world outside the self that needs attention, and a sense of confidence in the ability to contribute to that goal. The core pathology of inhibition refers to a self-conscious restraint or suppression of thoughts and behavior.

OBJECTIVE 6 Define the concept of school readiness, and analyze its relation to the developmental tasks of early school age. Summarize the obstacles that may prevent children from being able to adapt and learn in the school environment.

The applied topic of school readiness illustrates the potential conflict between development and socialization. Society has determined that 5-year-old children will attend school. At the same time, 5-year-olds are at a wide array of developmental levels, bringing them to the door of the school with substantial differences in physical, cognitive, social, and emotional competence. There is lack of agreement as to the definition of school readiness and how to measure it. Risk factors such as disabilities, poverty, and a non-English-speaking home environment may all complicate the child's ability to adapt to the school environment.

CASEBOOK

For additional case material related to this chapter, see the case entitled "Delaney Goes to Kindergarten," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman, pp. 87–94. This case illustrates some of the challenges that children face in the transition to kindergarten and how home, preschool, and kindergarten systems can work together to foster a child's continuing school success.



University of Michigan Museum of Art

A major theme of middle childhood is the mastery of new, valued skills. Among those skills most highly valued in modern cultures is reading, which opens the door to endless sources of knowledge, stimulates imagination, and connects children with worlds past and future.

LEARNING OBJECTIVES

1. Examine the role of friendship in helping children learn to take the point of view of others, be sensitive to the norms and pressures of the peer group, and experience closeness in relationships. Summarize the negative consequences that result from social rejection and loneliness.
2. Describe the development of concrete operational thought, including conservation, classification skills, mathematical reasoning, and the child's ability to understand and monitor his or her own knowledge and understanding.
3. Analyze the nature of skill learning, and examine societal factors that provide the contexts in which skill learning occurs.
4. Outline the factors that contribute to self-evaluation, including feelings of pride, self-efficacy, and ways that social expectations of parents, teachers, and peers contribute to a child's self-evaluation.
5. Summarize new levels of complexity in play as children become involved in team sports, examine the benefits of participation in sports, and analyze the cognitive and emotional development that accompanies team play.
6. Explain the psychosocial crisis of industry versus inferiority, the central process through which the crisis is resolved, education, the prime adaptive ego quality of competence, and the core pathology of inertia.
7. Evaluate the impact of exposure to violence on development during middle childhood.

Chapter Summary

— CASE STUDY Recollections of Childhood Friends —

In my life-span class, every so often I ask students to answer a question on an index card so that I can have a better idea about their own experiences and opinions. The following cards were written by college students in response to a question asking them to tell about a best friend or close friends from middle childhood.

"When I was a young boy, I played soccer. At soccer we were placed with boys who were the same age. I made a friend named S. who had a lot of the same traits as me. S and I played soccer together all through elementary, middle, and high school and we are still friends today. I am so happy that I played this sport and was able to make new friends that were like me." J. U.

"Since I have no siblings, and live across the street from my cousins, we are all very close. I have 5 cousins ranging from ages 18 to 26 now. When we were in middle childhood we would all hang out all summer together and just have fun. We were able to walk to the store down the street to get ice cream, and we were allowed to swim to the raft in the ocean near our houses. They were, and still are, my best friends. We have each other's backs and we all care about each other. We also would do anything for each other so we are all very loyal. Now that we are older, we don't get to see each other much because of work, college, and conflicting schedules. Back then were some good times." J. M.

"My best friend in middle school was a girl named L. We were best friends since kindergarten, so we were pretty inseparable. We were both very imaginative and everywhere we went we were making up strange games. We came up with ridiculous plot lines and character names and would act them out everywhere. We used all kinds of props—anything around us was part of the story. We had so much fun letting our imaginations take us away. We did everything together and her family felt like part of my family, and my family felt like part of hers. We were really more like sisters." C. M.

"My friendships during middle childhood were brutal especially during middle school. I was a part of a clique where one day you were making fun of someone, but the next day everyone was making fun of you. It was often stressful because I felt like I had to fit in and besides a select few I knew I could count on, I didn't feel like I had many real friends." G. J.

CASE ANAYLSIS Using What You Know

1. Based on these accounts, describe the important characteristics of friendships that are formed in middle childhood.
2. Compare and contrast the four narratives. What are some similarities and differences in childhood experiences of friendship?
3. Thinking back to your middle childhood, how would you describe you own close childhood friendships? How similar or different are they to these narratives?
4. Consider how the themes of middle childhood, including cognitive maturation, social competence, self-evaluation, and team play, are implicated in these narratives about friendship.
5. Speculate about how experiences with friends can contribute to the resolution of the crisis of industry versus inferiority.

For many children, middle childhood is a joyful, vigorous time. The fears and vulnerabilities of their early school days are behind them. Energized by ego qualities of hope, will, and purpose, most children are able to enjoy the resources and opportunities of their communities. Even as their family members continue to be a comfort to them, they begin to explore more complex social relationships with peers and other significant adults.

In some parts of the world, however, life in middle childhood is marked by extreme disorganization and exploitation. Children are vulnerable to the violence of war as victims of terrorist attacks, civil wars, injury from explosions of abandoned land mines, and forced enlistment as soldiers among warring tribes (Beah, 2007; Pearn, 2003). Slavers travel through impoverished areas, kidnapping, buying, or luring children into forms of slave-like labor where they are often beaten or sexually abused. Children of impoverished families are being sold or given away as slaves or bonded laborers. In many cultures, child marriage has become a form of enforced servitude; a condition that primarily impacts young girls (antislavery.org, 2016).

> Over 100 million children around the world work in hazardous conditions in agriculture, mining, domestic labor, and other sectors. On tobacco farms, children work long hours in extreme heat, exposed to nicotine and toxic pesticides that can make them sick. In Africa, Asia, and Latin America, child laborers in artisanal and small-scale gold mines work underground in pits that easily collapse and use toxic mercury to process the gold, risking brain damage and other serious health conditions. (Human Rights Watch, 2016)

According to the International Labor Organization (2012), 5.5 million children are in slavery, trafficking, debt bondage, and other forms of forced labor, forced recruitment for armed conflict, prostitution, pornography, and other illicit activities. An estimated 250,000 to 300,000 children are being used as soldiers, couriers, and sex slaves in armed conflicts in at least 14 countries around the world (Peace Direct, 2016). They not only witness bloodshed but also may be used as spies, messengers, informants, and "soldiers' wives" (Annan, Brier & Aryemo, 2009). In cities and towns suffering from ongoing armed conflicts, hundreds of thousands of children are unable to attend school and millions more are fleeing with their families to refugee camps. Over the past 4 years of civil war, an estimated 2 million Syrian children are now refugees, many living in makeshift camps (UNICEF USA, 2016).

In such circumstances, the opportunity for children to work on the developmental tasks of friendship formation, concrete operational reasoning, skill learning, self-evaluation, and team play may be viewed as a great luxury. We do not know much about the developmental outcomes for these children. Having the time, resources, and security to promote areas of cognitive, social, and emotional development is possible only in the context of communities that are economically and politically stable and ideologically committed to the intellectual and interpersonal future of their children. ●

Developmental Tasks

New developmental tasks emerge as children become focused on friendship formation, concrete mental operations, skill learning, self-evaluation, and team play. This mix of tasks coupled with new capacities for complex social, emotional, and intellectual activity produce a remarkable energy. Whereas play dominates the behavior of early-school-age children, middle childhood is characterized by more purposeful, industrious behavior such as earning money for completing chores; planning and building toys, gardens, or play spaces; or participating in competitions, performances, and community events. This is not to say that play is lost. New thrills and excitement accompany the capacity to engage in new forms of play and games, and taking new risks—riding one's bike farther from home, jumping and then diving into a pool from the high board, or riding on the big, fast roller coasters.

Friendship

OBJECTIVE 1 Examine the role of friendship in helping children learn to take the point of view of others, be sensitive to the norms and pressures of the peer group, and experience closeness in relationships. Summarize the negative consequences that result from social rejection and loneliness.

Can you remember some things about a friend you had when you were 9 or 10 years old? As you can tell from the opening case quotations, the **friendships** of middle childhood are often quite memorable. At this age, children describe **close friends** as people who play together, like the same activities, share common interests, enjoy each other's company, and count on each other for help. Peer relationships include forming meaningful dyadic and group relationships, participating in larger peer networks, and experiencing peer acceptance or rejection (Gifford-Smith & Brownell, 2003).

Friendships clearly provide social and developmental advantages (Berndt & Murphy, 2002; Hruschka, 2010). Human beings are social animals whose development is intricately dependent on a network of close, supportive social relationships. In middle childhood, the radius of significant relationships expands to include classmates, teammates, and close friends. According to evolutionary theory, being a member of a group has protective advantages. Group cooperation gives a selective advantage to many social species, especially in tracking and hunting for food. Therefore, the skills of cooperation and sociability may advance the species as a whole as well as the individual (Seligman, 2011). On an individual level, children who are able to participate in positive peer friendships are embedded in an intellectually and socially stimulating environment. For children who have caring, responsive relationships with their family members, friendships provide additional reassurance about being integrated into the social community.

Time with friends, whether in school, after school, or on weekends and vacation days, makes up a large part of a child's daily life. Friendships are not only important for companionship but also to keep loneliness at bay. The peer group is a microsystem in which diverse socialization processes are at work. Peers influence one another's self-concepts, emotions, moral beliefs and behaviors, engagement in skill-building activities, and attitudes about school. Experiences of peer acceptance and rejection have powerful and enduring consequences for children's physical and mental health as well as for their cognitive and emotional well-being (Bukowski, Castellanos, Vitaro, & Brendgen, 2015).

Family Influences on Social Competence

Not all children enter middle childhood with the same capacity to make friends and enjoy the benefits of close peer relations. Early family experiences, including the quality of a child's attachment, the family's approach to discipline, and the nature of family conversations, all contribute to a child's **social competence**. By social competence, we mean all the skills involved in the child's ability to form and maintain positive relationships with others (Bloom, 2009). Social competence includes the ability to alter one's behavior to conform to the norms and expectations for interactions in various settings and with different social partners. For example, a socially competent child can be friendly but not overly friendly with an unfamiliar child, or respectful but not overly intimidated by an unfamiliar adult. Social competence includes strategies for initiating an interaction as well as for sustaining and building an ongoing relationship. Social competence also involves the ability to manage occasional social difficulties, such as being teased, excluded, or ignored. The features of social competence change as children mature because the expectations for social behavior change with a child's age and the social settings a child is likely to encounter become more diverse.

Early Attachment and Social Competence. Children who have secure attachments in infancy appear to be more socially competent in preschool as evidenced by their greater popularity and their ability to engage more freely in social interactions. They are perceived as more helpful and better able to consider the needs of others. By middle childhood, the children who were securely attached in infancy have more friends than those with insecure attachments, have more positive interactions with their friends, and are more highly regarded by their peers. When two children with histories of secure attachments are friends with one another, those friendships are likely to be more responsive, less critical, and offer more companionship than friendships between children whose attachment history is mismatched (e.g., secure-insecure) (Berlin, Cassidy, & Appleyard, 2008; Thompson, 2008).

Peer relationships may be more difficult for children with insecure attachments. Children with insecure attachments are less likely to be perceived as leaders among their peers. Children with an avoidant attachment tend to be more aggressive and rejecting of their peers; they are more likely to engage in unprovoked hostile actions that push peers away. Children with a resistant (sometimes referred to as an ambivalent) attachment tend to be tentative, inhibited, and more likely to appear needy, a quality that may also result in peer rejection (Berlin, Cassidy, & Appleyard, 2008).

Parent–Child Interactions and Social Competence. Four ways that parents of securely attached children enhance their child's social competence include: (1) providing children with a greater number and a more diverse array of social experiences; (2) advising children on ways to develop and maintain positive relationships; (3) behaving in ways that provide children with role models for how to interact in sensitive ways with others; and (4) talking about emotions in an open, supportive style. Parents' discipline techniques, the way they speak to their child, and their parenting values are all linked to a child's development of social competence. Children whose parents interact with them in positive, agreeable ways by showing warmth, respect, empathy, interest, and affection, and who communicate frequently with their children are likely to have more positive friendship relations than children whose parents are harsh or neglectful (Biglan, Flay, Embry, & Sandler, 2012). These patterns are observable as early as preschool and continue to be found in the elementary grades.

Parents who use power-assertive, controlling discipline techniques and who believe that aggression is an acceptable way of resolving conflicts have children who expect to get their way by asserting power in peer conflicts (Deater-Deckard, Wang, Chen, & Bell, 2012; Malin, Cabrera, Karberg, Aldoney, & Rowe, 2014). A parent's discipline technique may influence what a child expects in a social interaction. Children who have been exposed to aggressive parenting or violence between their parents may believe that these same strategies will work to establish control and compliance with their peers. As a result, these children are more likely to have conflicts with their friends and to experience social rejection because of their aggressiveness.

Exposure to harsh and/or neglectful parenting in the early years is associated with a child's difficulties in emotional regulation, externalizing behaviors, and deceitful-callous behaviors, all of which make peer rejection more likely (Hallquist, Hipwell, & Stepp, 2015; Waller et al., 2012). Harsh parenting is typically associated with child aggression, and children's aggression is associated with a greater likelihood of peer rejection. However, there are some distinctions regarding both harsh parenting and child aggression that need to be considered when trying to understand their influence on children's peer friendships.

Variations in Harsh Parenting. First, harsh parenting can have a different impact on children when it is delivered by a parent who is emotionally controlled as compared to a parent who is out of control, administering the punishment in a context of rage (Deater-Deckard, Wang, Chen, & Bell, 2012). Second, harsh parenting can have a different impact on a child depending on the chaotic, disorganized, and stressful nature of the home environment (Vernon-Feagans, Willougby, Garrett-Peters, & the Family Life Project Key Investigators, 2016). Third, harsh parenting appears to have a different impact on children depending on whether it is delivered by mothers or fathers (Chang, Schwartz, Dodge, & McBride-Chang, 2003).

Variations in Child Aggression. First, exposure to family stress and harsh parenting can result in different adaptive coping strategies. In the context of highly stressful environments, children may become highly vigilant, always on the lookout for the next possible threat. In some children, this vigilance is associated with increased risk taking, impulsivity, hostile social competition, and reactive aggression. In other children, vigilance is expressed in social anxiety, lower risk taking and impulsivity, and fearful or withdrawn behavior (Del Giudice, Hinnant, Ellis, & El-Sheikh, 2012). These distinctions have sometimes been described as the Hawk and Dove reactions to stress (Sturge-Apple, Davies, Martin, Cicchetti, & Hentges, 2012). Still other children appear to block information related to stress altogether, ignoring information about dangers and threats in the environment. These children may be described as callous or deceitful; they are low in empathy and cooperation, and more likely to be impulsive and antisocial, with frequent proactive/instrumental aggression (Del Giudice, Hinnant, Ellis, & El-Sheikh, 2012; Waller et al., 2012).

Second, different forms of aggression have been described, especially relational aggression and physical aggression. Relational aggression might include gossiping, mean teasing, or social exclusion; it is less directly confrontational.

> If a girl gets mad at someone, they often don't tell the person, or at least not in a straightforward way. They let them figure it out by ostracizing them. . . . A quick way to ostracize a girl is to start a rumor about her, which may or may not be based in a nugget of fact. There also may be pressure in the group to not defend the girl if one of the group members hears someone else repeat the rumor. (Maybury, 2015 p. 12)

Physical aggression might include hitting, kicking, or pushing and shoving. Aggression can take the form of victimization such as threatening harm, taking a child's belongings, or embarrassing a child in front of others (Schwartz, Lansford, Dodge,

Peopleimages/E+/Getty Images

Relational aggression is more common among girls. Sometimes bullies gang up on a target, using the power of their peer support to intimidate or humiliate another child.

Pettit, & Bates, 2013). These various types of aggression are used differently by different children and have different consequences for peer acceptance, friendship, and rejection.

Third, there may be some adaptive advantages to certain types of aggression. Frequent physical aggression is generally associated with peer rejection, but a modest amount of physical aggression is not necessarily disruptive to peer relations. Relational aggression may have functional advantages for preserving social status and popularity in the peer culture. Children who are well liked by their peers, especially girls, are likely to increase their use of relational aggression, which in turn results in increases in peer acceptance. Girls who use a fair amount of relational aggression and little physical aggression are viewed positively by their peers (Ettekal & Ladd, 2015).

Children may directly imitate their parents' interpersonal communication styles and positive or aggressive behaviors. If parents ask a lot of questions and invite their child's opinions, for example, the child is more likely to show interest in others' ideas and opinions. One study asked children and parents to describe characteristics of parental conflict and related this to the child's friendship quality (Kitzmann & Cohen, 2003). Children who perceived their parents' conflicts as poorly resolved (e.g., "Even after my parents stop arguing, they stay mad at each other") also had difficulty resolving conflicts in their own close friendships. Children's perceptions of poor parental conflict resolution were correlated with lower friendship quality, including seeing their friends as less of a source of companionship, help, or intimacy.

Parents who are highly restrictive and who try to control their children's behavior are less likely to permit their children to have frequent or diverse peer social interactions. Children in these families may arrive at the middle childhood years with less experience in peer play (Hart, Ladd, & Burleson, 1990; McCloskey & Stuewig, 2001).

Sibling Interactions and Social Competence. Although parent–child relationships play an important role in the development of social competence, sibling relationships are also important. When asked about their close friends, many adolescents mention their siblings. Younger siblings are likely to be exposed to the toys, play companions, and play activities of their older siblings, bringing them into contact with more mature play partners at a young age. Depending on the age differences among siblings, many older siblings are expected to play a nurturing or protective role for their younger siblings, thereby advancing their own sense of responsibility and competence. Some families deliberately try to foster close sibling friendships by planning family activities and encouraging at-home playtime.

The study of sibling relationships is extremely difficult given the many possible configurations of sibling order, sibling spacing, sex composition of siblings, and family values regarding sibling relationships. There are few consistent results linking birth order to personality characteristics. What is more, relationships among siblings change over time as siblings develop new levels of social understanding.

It makes sense to consider that children learn patterns of peer interaction with their siblings that they bring to the larger arena of peer relationships at school or in the neighborhood. For example, firstborns are more likely to be self-assured in their position in the family whereas later-borns, having less power or authority, need to devise unique strategies to get their needs met or opinions heard.

Darrin Klimek/DigitalVision/Getty Images

These siblings are having a wonderful time together playing on a small stone beach. They are forging the basis for lifelong memories and friendship bonds. The younger sibs learn and benefit from advice from their older sibs; the older sibs enjoy their role as guides and mentors. The friendship among sibs may also be a source of support during their transition from childhood to adulthood.

Not all sibling relationships are close and comfortable. The more a child feels trusting and positive about his or her sibling, the more likely the relationship is to be characterized by high levels of openness and disclosure (Howe, Aquan-Assee, Bukowski, Lehoux, & Rinaldi, 2001). The more positive the quality of a sibling relationship, the more likely the siblings are to use compromise or reconciliation to resolve conflicts; conflicts between siblings who do not like each other are more likely to result in aggression or submission, often with one child in tears (Recchia & Howe, 2009). In contrast to children with siblings, only children have less experience handling the day-to-day conflicts that arise among siblings, leaving them less prepared to manage peer conflicts outside the family (Kitzmann, Cohen, & Lockwood, 2002). Results from two large studies find that in adulthood, people are likely to form close friendships and romantic relationships with other people of the same birth order (Hartshorne & Salem-Hartshorne, 2009). This is an indication that people learn patterns of social interaction in their sibling relationships that contribute to their social competence and provide a foundation for the establishment of intimacy.

Three Contributions of Friendship to Social Development

Children learn at least three lessons from daily interactions with their peers. The first lesson is an increasing appreciation of the many points of view represented in the peer group. As children play together, they discover that there may be several versions of the same song, different rules for the same game, and different customs for the same holiday. In learning about others through the friendly exchange of ideas, children also learn about themselves. The second lesson teaches children to be sensitive to the social norms and pressures of their peer group. The third lesson is the value of emotional closeness to a peer (Bukowski, 2001).

Perspective Taking and Cognitive Flexibility. The behavior of well-adjusted, competent children is maintained in part by a number of social cognitive abilities, including social perspective taking, interpersonal problem solving, information processing, and communicative competence. These cognitive abilities foster a child's entry into successful peer interactions. At the same time, active participation with peers promotes the development of these social cognitive abilities. In a longitudinal study of the influence of friendship on motivation and school adjustment, students who had a reciprocated friendship in sixth grade showed greater prosocial behavior, higher academic achievement, and less emotional distress than those who had no reciprocated friendship (Wentzel, Barry, & Caldwell, 2004).

You may recall the discussion of **perspective taking** from chapter 7 as one of the key factors that contributes to moral development, especially moral reasoning. As children interact with peers who see the world differently, they begin to understand the limits of their own points of view. Piaget (1932/1948) suggested that peers have an important influence in diminishing one another's self-centered outlook precisely because they interact as equals. Children are not forced to accept one another's ideas in quite the same way as they are with adults. They argue, bargain, and eventually compromise in order to maintain friendships. The opportunity to function in peer groups for problem solving and for play leads children away from the egocentrism of early childhood and closer to the eventual flexibility of adult thought. The benefit of these interactions is most likely to occur when peers have differences in perspective that result in conflicts that must be resolved. The benefits are especially positive for children who interact with slightly more competent peers who can introduce more advanced or flexible approaches to problem solving (Tudge, 1992).

Perspective-taking ability improves other social skills that contribute to the quality of a child's social relationships. Such skills include the ability to analyze social problems, recognize the emotional state of another person especially when that differs from their own emotional state, understand that others may view a situation differently because of their own information or beliefs, and accept individual differences in personality or abilities. Children who are sensitive to the variety of perspectives that coexist in a social situation are also likely to be more positively evaluated and trusted by their peers. Those who are perceived as more trustworthy and attuned to the concerns of others are likely to form more friendships (Rotenberg et al., 2004). An interactive process is thus set in motion. Children who have opportunities to participate in peer friendships make progress in achieving new levels of interpersonal understanding. As interpersonal understanding grows, children acquire the skills and sensitivity with which to be more effective with—and usually more valued by—their peers.

Social Norms and Peer Group Pressure. The peer group evolves **norms** for acceptance and **rejection**. As children become aware of these norms, they begin to experience pressure to conform to the peer group. Adults, particularly teachers, then lose some of their power to influence children's behavior. In the classroom, the early-school-age child focuses primarily on the teacher as a source of approval and acceptance. By age 9 or 10, children perceive the peer group as an equally significant audience. Children often *play* to the class instead of responding to the teacher. The roles of class joker, class snob, and class hero or heroine emerge during middle childhood and serve as ways of gaining approval from the peer group. Thinking back to the notion of relational aggression, you can see that some children use their knowledge of peer group norms to advance or preserve their social status. By spreading gossip, embarrassing children, or encouraging their friends to reject certain other children, they use social manipulation to sustain their power and prestige in the group.

The need for **peer approval** becomes a powerful force toward **conformity**. Children learn to dress, talk, and joke in ways that are acceptable to their peers. They learn to inhibit the expression of certain emotional reactions—especially sadness, vulnerability, and anger—in order to present a cool, competent public image to their peers (Salisch, 2001). Heterosexual antagonism, which is common at this stage, is perpetuated by pressures toward conformity. If all the fifth-grade boys hate girls, Johnny is not very likely to admit openly that he likes to play with Mary. Homophobic reactions are also evidenced at this age. Children who are gender atypical are often targeted for teasing, bullying, and social exclusion (Vaccaro, Kennedy, & August, 2012; Drury, Bukowksi, Vellásquez & Stella-Lopez, 2013). There are indications that perceived pressures to conform are stronger in the fifth and sixth grades than at later times, even though the importance of specific peer groups for group identity has not yet peaked (Gavin & Furman, 1989).

Close Friends. Peer acceptance and popularity are not the same things as having a close or best friend. To gain peer acceptance, children may need to conform to group norms for dress, behaviors, and attitudes; they may need to adhere to gender stereotypes in order to appear gender-typical; and they may have to conceal certain strong feelings or hide facts about their family (Gifford-Smith & Brownell, 2003). Close friends experience a more intimate level of disclosure, trust, and supportiveness. Close friendships are often measured through a *mutual nomination strategy*. Children are given a roster of the names of their classmates and asked to circle the names of children who are their friends. When two children circle each other's names, they are identified as friends. Close friendships are then identified by the children as those characterized by high levels of shared activity, companionship, help or guidance, and ease of conflict resolution (Asher & Paquette, 2003). In the context of these friendships, children share private jokes, develop secret codes, tell family secrets, set out on adventures, and help each other in times of trouble. They enjoy spending time together. They also fight, threaten, break up, and reunite.

In his theory of interpersonal psychiatry, Harry Stack Sullivan (1949) pointed out the significance of these early friendships as building blocks for adult relationships. Best friend relationships provide a degree of understanding and openness that is often not possible with parents or family members. Within these friendships, private thoughts and fantasies are shared without the worry of being judged as silly, gross, or impractical. It is significant that the child experiences love for and closeness to a peer rather than

Nancy Sheehan/PhotoEdit

Carly and Michelle have been best friends since first grade. They love to spend time together whether they're washing the dog, going for bike rides, or listening to music. They depend on each other for fun, support, and problem solving.

an adult. The relationship is more likely to allow for mutuality of power, status, and access to resources (Youniss, 1980). Conflicts in these close relationships may be worked out in terms that the children control. One child cannot take away another child's allowance or send the other child out of the room when a conflict arises. The children must resolve their differences within the framework of their commitment to each other.

The stability of close friendships is quite variable. Some children remain friends over several years despite changes in classrooms and schools; other children seem to be in different friendship relationships every few months. The structure of a school or classroom influences friendship formation and stability. Close friends often see each other during the school day in classes and extracurricular activities. In schools that promote stable classroom groupings, where children remain in the same homeroom or class group from one grade to the next, friendship groups also remain more stable (Neckerman, 1996).

Close friendships are influenced by attractiveness, intelligence, classroom social status, and satisfaction with and commitment to the best friend. In a study of more than 800 children in grades 3 to 5, 78 percent had at least one reciprocating best friend (i.e., one child named another as one of three best friends, and that other child named the first child high on the list as well), and 55 percent had a *very* best friend. More girls than boys had best friends, and the quality of their best friendships was somewhat different. Girls and boys described their best friend relationships quite similarly with respect to having low levels of conflict or betrayal and high levels of companionship and shared recreational activities. However, girls described their best friend relationships as having higher levels of caring and personal validation ("makes me feel good about my ideas"), intimacy ("we always tell each other our problems"), help and guidance ("help each other with schoolwork a lot"), and conflict resolution ("we make up easily when we have a fight") (Parker & Asher, 1993).

Girls and boys have somewhat different expectations about close friends. Girls tend to disclose more than boys about their worries and personal feelings. This seems to be related to how they feel about disclosure. Girls are more likely than boys to expect that by disclosing they will feel cared for and understood. Boys are more likely to feel weird about disclosing and see it as a "waste of time" (Rose et al., 2012). When asked to respond to a fictional scenario in which a close friend disappoints them by betraying a confidence, being unreliable, or failing to provide support or help, girls were more troubled by these transgressions than boys. Boys and girls were equally likely to say they would use some strategies to get revenge, but girls were more likely to say they would feel either sad or angry. These studies suggest that although having a close friend is highly valued for both boys and girls, the dynamics of these relationships are gendered (MacEvoy & Asher, 2012).

Having a close friend provides joyful experiences of companionship and feelings of being understood. As such, close friends can also play a protective role, reducing the impact of negative experiences. When a best friend is present during a negative experience, the experience itself seems to arouse less anxiety and is less damaging to a child's self-concept (Adams, Santo, & Bukowski, 2011). Children who have at least one best friend are less likely to experience depressive symptoms. Even among children who are characterized as withdrawn or inhibited, having at least one close friend seems to prevent the escalation of depression over time (Bukowski, Laursen, & Hoza 2010).

Loneliness

With the increased importance of friendship and peer acceptance come the risks of peer rejection and feelings of loneliness. In the period from preschool to middle childhood, issues of shyness, social anxiety, and peer victimization become increasingly salient. Experiences of social rejection or dissatisfaction in friendship quality become linked to a more general sense of anxiety in the school environment and a decline in self-worth (Asher & Gazelle, 1999; Asher, Parkhurst, Hymel, & Williams, 1999; Fordham & Stevenson-Hinde, 1999). By third grade, some children are characterized as anxious and solitary. They are shy, typically watching their peers without joining in, wanting to interact with their peers but afraid that they will be socially awkward or will not be accepted (Rubin, Coplan, & Bowker, 2009).

Three social characteristics combine to increase a child's experiences of **loneliness**. First, children who are anxious and solitary have trouble forming close friendships that provide emotional closeness and companionship; they are more likely to feel lonely. It is not necessary to have many friends. However, children who have at least one enduring, high-quality friendship are less likely to experience loneliness (Nangle, Erdley, Newan, Mason, & Carpenter, 2003).

Second, some children are systematically excluded. They don't get invited to children's parties or are the last to be chosen for teams. Peer rejection is especially powerful in producing feelings of loneliness. The relationship between peer rejection and loneliness has been found across countries and grades from kindergarten through middle school (Asher & Paquette, 2003; Crick & Ladd, 1993).

iStockphoto.com/huronphoto

Lily is feeling sad and lonely. Her best friend said she doesn't want to play with her anymore; the other kids in the neighborhood laugh at her; and her mom told her to go outside and play because she needs to get some work done in the house.

Third, among the children who are anxious and solitary, those who experience exclusion or are rejected by peers become increasingly socially helpless, anticipating rejection and being unwilling to take new risks to reach out or initiate social exchanges (Gazelle & Druben, 2009). Children who tend to blame themselves for their lack of social acceptance feel more lonely and are less likely to believe that they can do anything to improve their situation. Those who are withdrawn, victimized, or bullied report higher levels of loneliness than other unpopular children (Kochenderfer-Ladd & Wardrop, 2001).

Although loneliness can be a transient experience, as when children move from one neighborhood or school to another, or when a best friend moves away, some children are chronically lonely. They may have unrealistic expectations about friendship and intense worries about the possibility of negative peer evaluations (MacEvoy, Papadakis, Fedigan, & Ash 2016). These children have strong negative emotional reactions to social messages of exclusion and tend to be suspicious of efforts to include them. They view social exclusion as evidence that there is something inadequate about them. Thus, their perceptions and attributions about social cues reinforce their reticence and increase feelings of loneliness (Vanhalst et al., 2015).

What can lonely or socially anxious children do to increase their sense of closeness to friends? **Cognitive restructuring** techniques may help children deal with social anxiety (Rapee, Wignall, Spence, Lynham, & Cobham, 2008). The central features of cognitive restructuring are (1) identify the thoughts that increase strong emotions such as anger, anxiety, or sadness; (2) challenge their accuracy; and (3) replace them with interpretations that are more realistic and less disruptive to adaptive behavior.

With regard to **social anxiety**, students learn to monitor changes in their anxiety level and to become aware of the thoughts that accompany this increase in anxiety. For example, a student may recognize that his anxiety rises in class when he thinks about answering a question out loud because he assumes that his classmates would think he is stupid if he were to give an incorrect answer. Once these assumptions have been identified, the student may be guided to look for evidence that these assumptions are correct and to consider alternative interpretations. The student may be encouraged to take a more accepting view, recognizing that everyone makes mistakes. When other students make mistakes, he does not usually think badly of them. To strengthen this perspective and remain calm, the student might practice self-talk, such as, "It's OK to make mistakes; that's how we learn." Through cognitive restructuring, socially anxious students learn to recognize the sources of their anxiety and practice strategies for redefining the situation so they can be more confident about taking the initiative in peer situations.

Some children have discovered that online communication provides an environment where they can experience greater levels of self-disclosure and depth of communication with friends. The Internet is increasingly used as a way to supplement face-to-face friendship interactions through a variety of social media including Facebook, Twitter, Instagram, texting, blogs, email, and instant messaging (Peter, Valkenburg, & Schouten, 2005; Walther, 2011). Although some children use the Internet to participate in chat with strangers, most use it to maintain their existing network of friends. Some form friendships with strangers through chat who then become face-to-face friends. In a study of Dutch children, 61 percent of the participants who were 10 and 11 years old used the Internet for online communication. Almost 90 percent of those children communicated with preexisting friends (Valkenburg & Peter, 2007). Children who described themselves as either lonely or socially anxious were more likely to perceive online communication as facilitating greater breadth and depth of communication. Those socially anxious children who perceived the Internet as offering a way to achieve greater intimacy in communication used the Internet more often and described their friendships as closer than socially anxious children who used online communication infrequently.

Socially anxious children may have more difficulty with face-to-face self-disclosure. For these children, the value of the Internet is not for increasing general social interaction or for forming new relationships but for allowing greater levels of intimacy with existing friends, unencumbered by the difficult visual and auditory cues that may disrupt disclosure in face-to-face interactions. Unfortunately, online technologies and text messaging can also be used in a hostile way to send messages of rejection, such as with cyberbullying. Youth can use electronic media to embarrass, harass, or threaten their peers.

Rejection

Rejection hurts. Studies of rejection find different patterns of reaction, including emotional numbness, changes in mood reflecting new levels of sadness or feeling bad, and decreases in self-esteem. Two basic needs appear to be thwarted when a child experiences social rejection—the need for control and the need for belonging. Under some conditions, children protect themselves from the negative feelings associated with rejection by withdrawing from social interactions; in other conditions they may act aggressively to try to reassert control (Baumeister, DeWall, & Vohs, 2009; Gerber & Wheeler, 2009).

Research has identified three types of children who experience peer rejection. Some children who are rejected are disruptive and aggressive with their peers; others are socially withdrawn but do not exhibit aggressive tendencies; a third group has been described as both aggressive and withdrawn (French, 1988, 1990; Hymel, Bowker, & Woody, 1993). Children who are physically aggressive are identified as early as toddlerhood. Aggressiveness has been noted as a feature of personality that is linked to difficulties in emotional regulation, exposure to power-assertive or harsh parenting, and reduced levels of empathy. Genetic and environmental factors combine to support a child's aggressive and oppositional behavior (Burt & Neiderhiser, 2009). **Aggressive-rejected** children, often referred to as *bullies*, are more likely than nonaggressive children to attribute hostile intentions to others. They see peer interactions as threatening and say they would be likely to use aggressive strategies in response to negative peer behaviors (Quiggle, Garber, Panak, & Dodge, 1992; Waldman, 1996). Aggressive-rejected children tend to have an exaggerated idea of their competence and social status. They are less accurate in reading their own social status among their classmates, although they are just as accurate as other children in reading the social status of others (Zakriski & Coie, 1996).

However, not all aggressive children are rejected. One study looked at the relationship of antisocial and prosocial characteristics of young children and their social standing in the classroom (Farmer & Rodkin, 1996). Children in four different types of classroom groups were compared: academic giftedness, emotional and behavioral disorders, general education, and learning disabilities. Across all four types of classrooms, aggressive, disruptive characteristics were strongly associated with peer rejection or isolation for girls. For boys in the general education classes, however, aggressive behavior was positively associated with popularity. In some classroom contexts, aggressiveness, particularly among boys, may be a viable path toward bonding with other boys and asserting one's leadership, especially for boys who cannot achieve notice through their academic performance (Ettekal & Ladd, 2015; Poulin & Boivin, 2000). In many cases, bullies deliberately choose targets who are already rejected by their peers, thus minimizing the risk of social rejection from other children. Moreover, boys who bully other boys are admired by some girls who are possibly being attracted to this gender-stereotyped dominant male behavior (Dijkstra, Lindenberg, & Veenstra, 2007; Veenstra, Lindenberg, Munniksma, & Dijkstra, 2010).

Children in the **withdrawn** group tend to be inhibited, anxious, and interpersonally reserved. They have a negative self-concept and tend to interpret negative peer reactions as resulting from their own personal failings (Hymel et al., 1993). They have difficulty dealing with stress. These children may exhibit inappropriate emotions and display various unusual behavioral mannerisms that are likely to draw ridicule from their peers (French, 1988). Withdrawn, non-aggressive rejected children were paired with popular children in a problem-solving and reasoning task. The withdrawn rejected children demonstrated difficulties in collaboration and communication that may help account in part for their social isolation (Crosby, Fireman, & Clopton, 2011). Studies of children with developmental disabilities and language disorders suggest that these children begin to have more relationship problems in the upper elementary school grades. As their social status among classmates declines, they may become targets of bullying, and they are less likely to be involved in reciprocal friendships. Over time, children who experience a combination of anxiety, lack of a close friend, and peer victimization are likely to continue to be targets of victimization (Asher & Gazelle, 1999; Gazelle, 2008; Goldbaum, Craig, Pepler, & Connolly, 2003).

Children in the **aggressive-withdrawn** group tend to be the least well liked of all three types of rejected children. They exhibit anxiety, poor self-control, and social withdrawal in addition to aggressive behavior. They are rated by other children as incompetent in school ability; unattractive; showing the poorest skills in leadership, cooperation, or sense of humor; and the most likely to behave inappropriately in school. Aggressive-withdrawn children are similar to the bully-victims described in the **Applying Theory and Research to Life** box Bullying (Marini, Dane, Bosacki, & YLC-CURA, 2006). Having been excluded or rejected by their peers, they respond by lashing out against children who are more vulnerable than they. Despite high levels of peer rejection, aggressive-withdrawn children do not have the same low self-concept and negative view of their abilities as the withdrawn children. They are likely to have future adjustment problems and often require psychiatric treatment in adolescence or adulthood (Coie & Krehbiel, 1984; Hymel et al., 1990).

Peer rejection has consequences for mental health and school adjustment. Children with problems in attention and self-regulation may become targets of peer victimization in the early school grades. The anxiety and distractions caused by this hostile peer environment can increase the demands on a child's self-regulation resources, making initial difficulties with hyperactivity, inattentiveness, and behavioral regulation worse. Beginning in the early school grades, peer rejection is associated with school problems, including school avoidance, negative attitudes about school, less engagement with school-related tasks, and a less cooperative orientation toward teacher requests and group activities. The longer this peer rejection lasts, the more impact it seems to have on a child's engagement with the learning environment and the academic challenges of school (Ladd, Herald-Brown, & Reiser, 2008; Schwartz, Lansford, Dodge, Pettit, & Bates, 2013; Stenseng, Belsky, Salicka, & Wichstrøm, 2016).

FURTHER REFLECTION: *Analyze the relationship of social competence and friendship. Describe some ways that a child's social competence contributes to the quality of friendship in middle childhood. Describe some ways that a child's friendships might enhance social competence.*

Given what you have read about loneliness and rejection, think about what might be done to help improve social competence among children who lack adequate social skills.

APPLYING THEORY AND RESEARCH TO LIFE

Bullying

Bullying is a common problem facing children in many cultures. Building on the work of Dan Olweus (1978, 1995), the Centers for Disease Control and Prevention (CDC) and the Department of Education offered a federal definition of bullying which includes three elements: "unwanted aggressive behavior; observed or perceived power imbalance; and repetition of behaviors or high likelihood of repetition" (stopbullying.gov, 2014). Bullying can take many forms such as physical harm, verbal threats, harming a child's reputation, ostracizing a child, or victimizing a child (for example by taking their belongings). Relational bullying is the most common form, such as name calling, teasing, and spreading rumors or lies. Physical bullying is next most common, and cyberbullying is least common (Bradshaw, Sawyer, & O'Brennan, 2007). Given the variety of forms that bullying can take, the age of the respondents, and the form of assessment, the prevalence of bullying is difficult to determine (Hymel & Swearer, 2015). The government website referred to above estimates that between 25 percent and 33 percent of children have been bullied at school, and as many as 30 percent of students admit to bullying others. In a national survey of parents' worries and concerns about their children, 60 percent were worried that their child might be bullied (Pew Research Center 2015c).

Bullying is most common in middle schools. Over 70 percent of school staff have observed bullying in their schools, with over 40 percent saying they have witnessed bullying once a week or more (Bradshaw et al., 2007). Although cyberbullying is less common than other forms, it can have a far-reaching impact. **Cyberbullying** involves "intimidation , hurt or harassment conducted using cell phones, the Internet or other electronic devices" (Svoboda, 2014). When an insult, threat, photo, or rumor is started online, it can spread through a network of contacts, allowing people to continue the bullying without any consequences. Meanwhile the victim may experience the insult over and over, unable to remove the message or stop the spread of the attack.

What are the characteristics of bullies and their victims? There appear to be two types of bullies, those who are socially integrated and enjoy a degree of peer popularity, and those who are marginalized and lack peer acceptance (Juvonen, Graham, & Schuster, 2003; Olweus, 1978; Rodkin, Espelage, & Hanish, 2015).

Socially Integrated Bullies. These children are identified by their peers as higher than average in aggression and low in victimization. Classmates often perceive them as "cool" but do not want to spend much time with them (Juvonen et al., 2003). Boys may be physically stronger than their peers; girls may be socially more popular. They have deep-seated needs for power and enjoy being in control. They are likely to have experienced a family environment characterized by harsh discipline or love withdrawal as well as indifference, low involvement, and lack of warmth. This context results in little sense of personal empathy and a high degree of hostility toward others. They have learned early in life that aggression is a tool for controlling others. These children are often aggressive toward teachers and other authority figures as well as toward peers.

It is not uncommon for aggressive boys to have best friends who are also aggressive. Within these relationships, the boys encourage each other toward rule breaking (Bagwell & Coie, 2004). Socially integrated bullies often find some reward or reinforcement for their behavior, especially when they coerce their victims into giving them money, taking things of value, and being treated with respect by other peers. For some, even the pain or humiliation they observe in their victims can be a rewarding source of satisfaction (American Society for the Positive Care of Children, 2016). The fact that bullies enjoy both high social status and report few psychological problems helps explain why bullying is so hard to modify. Bullies enjoy their social reputation and, although feared by others, do not seem to be bothered by the fact that many of the children avoid them.

Socially Marginalized Bullies. These children are described by their peers as both high in aggression and high in victimization (bully-victims). Socially marginalized bullies have themselves been targets of exclusion or victimization. As a result, their bullying may be an attempt to gain some control or to retaliate in a system that they perceive as rejecting or humiliating. In contrast to socially integrated bullies, bully-victims are more depressed and lonely, have lower social status, are less popular, and are more likely to be avoided by their classmates. Over time, they are likely to become increasingly friendless (Kechel, Ladd, Bagwell, & Yabko, 2015). These bullies are often described as "at risk" students who have negative attitudes about themselves and a tendency to perceive others as threatening or hostile toward them (Juvonen et al., 2003; Rodkin et al., 2015). Having been victimized by others, they may subsequently lash out to express a desire for revenge (American Society for the Positive Care of Children, 2016). In some cases, these marginalized children have been victimized at home as well as at school, resulting in a sense of being overwhelmed by unmanageable threats (Schwartz, Lansford, Dodge, Petit, & Bates, 2013).

Victims. If bullying involves a power differential between the bully and the victim, we can infer that in a specific school environment certain children are victimized because of a relative lack of essential resources. Victims may be singled out due to disabilities, gender atypicality, comparatively lower income, or due to personality qualities like shyness or low self-esteem. In comparison to the bullies, the victims, especially boys, are physically weaker. When attacked, they do not retaliate. As a result, the abuse continues and often escalates. Children who are perceived by their peers as victims also report the highest levels of depression, social anxiety, and loneliness; have the lowest social status as rated by peers; and are described by teachers as the least popular of the children (Juvonen et al., 2003). They are the most marginalized of the children, and, as a result, may be additionally vulnerable because they have no classmates who will defend them or intervene when they are being attacked.

Sexual orientation and race/ethnicity are two factors that are commonly intertwined with bullying. LGBTQ students are targets of frequent bullying. Surveys of LGBTQ youth find that 80 percent say that their teachers never or rarely intervened to stop homophobic joking or bullying (SPLC Report, 2010). Children who are members of a numeric ethnic minority in their school are more vulnerable to harassment than children who are in the ethnic majority. When a school is ethnically diverse and no group is in a clear numeric majority, children who are victims of bullying are more likely to attribute the problem to the bullies or to conditions of the school environment that allow this kind of harassment than to blame themselves (Graham, 2004; Graham & Juvonen, 2002).

Intervention. The complex social dynamics surrounding bullying call for a multidimensional approach to intervention. In order to be effective, interventions need to be sensitive to the microsystem in which the bullying is taking place. Who are the bullies? Who are the victims? Are there ethnic, gender, religious, social class, or sexual orientation issues involved? Is there evidence that bullies are being rewarded with social capital? If so, how does the intervention infiltrate the social reward system of the peer group? (Rodkin et al., 2015).

To date, evaluations of anti-bullying programs have reported modest success in preventing bullying and reducing victimization in schools (Ansary, Elias, Greene, & Green, 2015). In designing programs, one needs to be clear about the focus of the intervention. Violence prevention, harassment prevention, and bullying prevention are related, overlapping concepts, but programs focusing on one may not adequately address the others (Cornell & Limber, 2016). Some programs focus on prevention of bullying; others on addressing bullying once it has occurred. Some interventions are intended to support children who have been victimized to prevent long-term social, academic, health, and mental health consequences (Juvonen, Schacter, Sainio, & Salmivalli, 2016).

Four key areas need to be addressed in any effective bullying intervention (Ansary et al., 2015):

1. An overall holistic theoretical approach that addresses both in-school and out-of-school contexts and strives to create a positive school climate involving students, administrators, teachers, staff, and families.
2. Specific content areas, including social-emotional development, conflict resolution, character development, and efforts to increase "upstander" behavior that encourages others to speak out and intervene when they observe bullying.
3. Leadership and team management, including teacher/staff/administrator training, and clear policies for addressing bullying when it occurs.
4. Systematic use of assessments to understand the extent of bullying and victimization in the school, monitor program implementation, and improve effectiveness.

Critical Thinking Questions

1. Why do you think that some bullies are popular and have high status among their peers? Hypothesize about the implications of having popular bullies for the nature of the school climate.
2. What might be some consequences of being a victim of bullying? Summarize how being a victim affects subsequent school achievement, peer relationships, and mental health.
3. Predict the likely trajectories for bullies as they move into adolescence and adulthood. What factors might influence whether being a bully in middle childhood continues to be expressed in some fashion in later stages of life?
4. What strategies can you think of that would improve the school environment for LGBTQ students and reduce the chances that they are victims of bullying?
5. Imagine that you are asked to evaluate a school-based program to prevent bullying. What outcome measures would you select? In other words, what would you consider evidence that a program to prevent bullying was effective?

Concrete Operations

OBJECTIVE 2 Describe the development of concrete operational thought, including conservation, classification skills, mathematical reasoning, and the child's ability to understand and monitor his or her own knowledge and understanding.

Children's abilities to analyze and manage social relationships, including friendships, are linked to their ability to solve other kinds of problems. Advances in reasoning about the physical world may stimulate new ways of handling complex social situations; similarly, engaging in complex social situations may enhance the child's ability to bring flexibility and perspective to problems of the physical world. Observations across many different cultures confirm a shift in adults' expectations of children at around age 7, suggesting a convergence of advanced cognitive capacities and new cultural demands. By middle childhood, children are expected to be able to coordinate their thinking with others, cooperate with the group, and use ideas and information to solve applied problems (Gauvain & Reynolds, 2011).

Thinking back to the period of infancy, the discussion of intelligence focused on the establishment of sensory and motor patterns used to explore the environment, manipulate means–end relationships, clarify the nature of physical objects, and form simple categories. During toddlerhood, cognition moves beyond the experiential domain as children develop a variety of representational skills that free them from complete reliance on their immediate physical environment. Toddlers create novel situations and solve problems by using thought, fantasy, and language. Piaget (Piaget & Inhelder, 1969) suggested that at about age 6 or 7, a qualitatively new form of thinking develops, referred to as **concrete operational thought**. This type of reasoning guides thought by imposing logical rules on one's judgments, leading to the acceptance of certain inferences that adhere to the logic as more compelling or convincing than others (Moshman, 2004).

The word **operation** refers to an action that is performed on an object or a set of objects. A **mental operation** is an action that is carried out in thought rather than in behavior. Piaget argued that such mental operations are built on some physical relationship that the younger child can perform but cannot articulate. For example, a toddler can arrange a graduated set of circles on a stick so that the largest circle is at the bottom of the stick and the smallest circle is at the top. The child does not have a verbal label for the ordering operation but can perform it. With the emergence of concrete operations, children begin to consider a variety of actions that can be performed on objects and can do so mentally without having to do them physically. Thus, a mental operation is a representation or scheme for an alteration in the relationships among objects.

One of the most powerful mental operations is *reversibility*. One can imagine an action, such as filling a glass with water and then undoing the action by emptying the glass. One can even imagine adding salt to water and then removing the salt, even though this would be difficult in practice. In contrast to sensorimotor schemes, which unfold in a behavior sequence, operations can be done and undone in the mind (Newman & Newman, 2007).

Piaget (1972a) used the term concrete to contrast this quality of thinking to the more hypothetical reasoning of adolescents and adults. The child reasons about objects and the relations among them but has difficulty entertaining hypothetical statements or propositions. Thinking is typically focused on real objects that exist in the world, even if the child is not seeing or manipulating these objects at the moment. For example, children can reason about problems involving the grouping of trees into different categories and identifying the features of these categories. However, if you pose a problem involving trees that migrate from North to South with the seasons, a child in the concrete stage of thinking will have difficulty even entertaining the problem because trees do not migrate. During the stage of concrete operations, the three conceptual skills that have received the most attention are (1) conservation, (2) classification, and (3) computational skills; these are explained briefly in Table 8.1. Over the period of middle childhood, children apply these skills to achieve a clearer understanding of the logic, order, and predictability of the physical world. As children take a new approach to problem solving through the use of the logical principles associated with concrete operational thought, they generalize these principles to their thinking about friendships, team play and other games with rules, and their own self-evaluation. Children are able to consider two competing explanations, look at a problem from another person's point of view as well as their own, and, using this information, plan a strategy to reach a goal.

Conservation

The basic meaning of **conservation** is that physical matter does not magically appear or disappear despite changes in form, shape, or container. The concept of conservation can be applied to many dimensions, including mass, weight, number, length, and volume. A child who conserves is able to resist perceptual cues that alter the form of an object, insisting that the quantity remains the same despite the change in form. One of the most common problems of this type that Piaget investigated involves *conservation of mass*. The child is presented with two clay balls and is asked to tell whether or not they are equal. Once the child is satisfied that the balls are equal, one of them is flattened out into a pancake. The child is then asked, "Which has more—this one [the pancake] or this one [the ball]?" Sometimes, the child is also asked whether the clay pieces are still the same. The child who does not conserve might say that the pancake has more clay because it is a lot wider than the ball. This child is still in the preoperational stage of thought: She is using personal perceptions to make judgments rather than logic. In contrast, the child who conserves knows that the two pieces of clay are still identical in mass and can explain why.

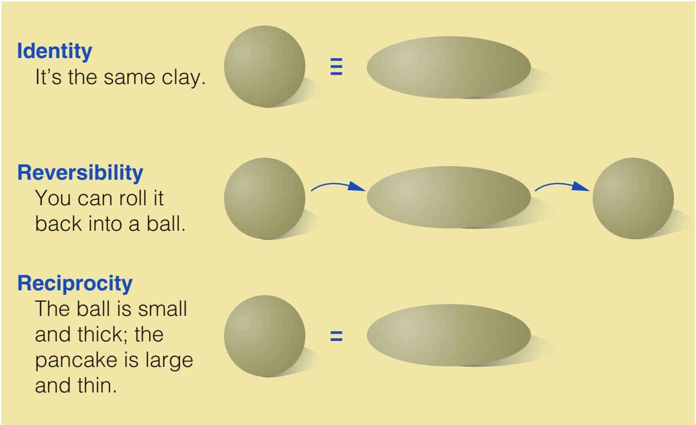
Tony has created a plan and is focusing seriously on how to implement his plan as he builds his brick structure. The combination of fine motor skills, computational skills, and logical reasoning come together in the design of his project. For many children, materials that offer opportunities to design and build new structures are a source of satisfaction throughout middle childhood.

Children eventually use the three concepts illustrated in FIGURE 8.1 ▶ to ascertain that equality in any physical dimension has not been altered. First, the child may explain that the pancake has the same amount of clay as the ball; no clay has been added or taken away. This is an example of the concept of **identity**: The pancake is still the *same* clay, and nothing has been



Identity
It's the same clay.

FIGURE 8.1 ▶ Three Concepts That Contribute to Conservation

changed except its shape. Second, the child may point out that the experimenter can turn the pancake back into a ball. This is an example of the concept of **reversibility**. The child realizes that operations can be reversed so that their effects are nullified. Third, the child may notice that, although the pancake has a larger circumference, the ball is much thicker. When the child can simultaneously manipulate two dimensions, such as circumference and thickness, we observe the concept of **reciprocity**. In the clay ball example, change in one dimension is compensated for by change in another; the total mass remains the same. With consolidation of the concepts of identity, reversibility, and reciprocity, the child is able to conserve in any physical dimension. Children generally conserve mass and number earliest, weight later, and volume last.

Conservation may not generalize across all of the physical modes. For example, children who are unable to conserve quantity in an unfamiliar object, such as poker chips, can do so with a more familiar one, such as M&M's (Gulko, Doyle, Serbin, & White, 1988). In one study, girls were able to perform a conservation of liquid task when it was presented in the standard manner of comparing the experimenter's glass and their own. However, when the task was embedded in a story where juice had to be divided between two dolls, their performance declined. Evidence of a lack of generalizability of knowledge from in-school to out-of-school contexts is found in other areas of reasoning, especially mathematical codes and scientific principles (Perret-Clermont, Perret, & Bell, 1991).

Extensions of Piaget's Ideas About Conservation.

Researchers have raised questions about the meaning of conservation tasks, the timing of the emergence of conservation, and the possibility of teaching children to conserve. The way the task is presented and the kinds of questions asked may influence a child's responses. For example, the task may emphasize identity or equivalence. In an *identity* task, the child is asked to judge whether a single clay ball has the same amount of clay after it has been rolled into a sausage. In an *equivalence* task, there are two balls of clay. The child is asked to judge whether the ball that is rolled into a sausage has the same amount of clay as the standard, comparison ball. Some studies have shown that children can perform the identity task earlier than the equivalence task; others have shown the opposite; and still others have argued that identity and equivalence are achieved at the same time (Silverstein et al., 1982). In a study of 5- to 7-year-olds, children were asked to tell how the materials looked and then to tell how they really were. Giving the child this distinction between appearance and reality resulted in more correct answers than the standard procedure in which this distinction was not made (Bijstra, Van Geert, & Jackson, 1989). Approaches to instruction, including the use of gestures, the variety of materials, and the specific language used to present the problem all contribute to a child's ability to reason about conservation (Ping & Goldin-Meadow, 2008).

Piaget's view that children will enter the stage of concrete operational reasoning through active construction and experimentation at around the age of 6 or 7 is not universally true. In a study of the relationship of conservation of liquid and early mathematical skills, researchers found that only about half the 6 and 7 year olds could conserve volume (Wubbena, 2013). In a study of fifth graders, half the students were identified as being in the preoperational stage, even at age 10. The study examined strategies for enhancing concrete operational reasoning through guided intervention involving special activities intended to promote logical problem solving and abstract thinking. This intervention was found to be successful in promoting concrete operational thought (Bakken, Thompson, Clark, Johnson, & Dwyer, 2001).

Theoretically, Piaget's view of development suggests that there is a period of maturational readiness for the application of logical operations to physical objects. When left to their own exploration and experimentation, Piaget argued, children would discover the regularities and operations that underlie conservation. Showing a child a conservation problem and then explaining and reinforcing the correct answer should not be very effective if the child is not ready to assimilate this information. However, research has shown that it is possible to train young children of preschool age to conserve. Early training studies have both theoretical and practical implications. They demonstrate that it is possible to introduce such concepts as identity and reversibility so that children as young as 4 can achieve conservation. Children also transfer conservation from the tasks involved in training to other materials and dimensions (Field, 1981; May & Norton, 1981).

One way to advance a child's approach to conservation is to confront the child with alternative reasoning. For this contradiction to be effective, however, the child must be approaching a level of readiness to reorganize his thinking, and the gap between the child's current level of reasoning and the new ideas must not be too great. This reminds us of Vygotsky's concept of the zone of proximal development. The implication is that entry into a new stage of thought may emerge earlier and may be more readily influenced by the social environment than Piaget's cognitive developmental theory predicts. However, Piaget himself was not especially impressed by faster and sooner. He believed in the enduring benefits of personal discovery.

Practically speaking, research has demonstrated that preschool- and kindergarten-age children can integrate and apply more abstract concepts than educators once believed they could. For example, studies of children as young as 3 and 4 have shown that they understand the idea that materials are made of tiny particles that retain their properties even when they are invisible. They can use this notion of particles to explain how a substance, such as sugar, continues to exist in a solution and retain its sweetness even when it is invisible (Au, Sidle, & Rollins, 1993; Rosen & Rozin, 1993). In a study focused on estimating volume, many children in kindergarten and first grade were able to consider the integration of three dimensions—height, width, and depth—to guess how many small cubes would be needed to build a larger cube. Their estimates suggest that at even this young age, children can integrate information from three dimensions (Ebersbach, 2009). Early childhood educators have found that through a planned program of exploring, experimenting, and describing the transformation of materials, young children can be guided to conceptualize the physical world in a systematic, logical manner.

Classification Skills

Classification was first discussed in chapter 5, describing infants' basic categorization skills. **Classification** is the ability to identify the properties of categories, relate categories or classes to one another, and use categorical information to solve problems. Two components of classification provide the essential ability to apply knowledge from a known or familiar instance to a new instance: categorization and induction. **Categorization** simply means that if one apple belongs to the category of fruit, then *all* apples are fruit. You do not need to learn this categorization label for each type of apple. **Induction** refers to the realization that whatever holds true for one member of a category is likely to hold true for other members as well. For example, water and juice are both liquids. If you can pour water, you can pour juice. Other substances classified as liquids should also have this property—even substances one has never seen. The value of classification skills is not merely to organize objects or experiences into classes, but to take advantage of what is known about these categories to make inferences about the characteristics and dynamics of members of the same categories, members of hierarchically related categories, and objects that are not members of a specific category (Farrar, Raney, & Boyer, 1992; Kalish & Gelman, 1992; Lopez, Gelman, Gutheil, & Smith, 1992).

One component of classification skills is the ability to group objects according to some dimension that they share. Another component is the ability to order subgroups hierarchically so that each new grouping will include all previous subgroups. Vygotsky (1962) suggested a method for studying classification in young children. Children are presented with a variety of wooden blocks that differ in shape, size, and color. Under each block is a nonsense syllable that is hidden from view. The children are instructed to select, one at a time, all the blocks that have the same syllable. The youngest children, who would be characterized as preoperational in Piaget's stage theory, tend to select blocks by their color. Their technique for grouping is highly associative. They choose each new block to match some characteristic of the previous selection, but they do not hold in mind a single concept that guides their choices.

In the stage of concrete operations children tend to focus on one dimension at first, perhaps shape, and continue to select blocks until they discover that they have made an incorrect choice. They use this discovery to change their hypothesis about which characteristics of the blocks are associated with the nonsense syllable. This classification task demonstrates the child's ability to hold a concept in mind and to make a series of decisions based on it. It also demonstrates that during the stage of concrete operations, children can use information from their mistakes to revise their problem-solving strategy.

Piaget studied reasoning about class hierarchies or class inclusion by asking questions about whether a group of objects included more members of one subtype than of the group as a whole (Piaget, 1941/1952; see also Chapman & McBride, 1992). Thus, when a set of pictures shows three ducks, six sparrows, and two robins, one might ask, "Are there more sparrows or more birds in these pictures?" This is an unusual kind of question, one that children are rarely asked. By the age of 8 or 9, however, many children can respond correctly because they recognize the distinction between classes and subclasses. In order to handle such problems, children have to inhibit their tendency to reinterpret the question in line with a more common comparison, such as, "Are there more sparrows than ducks?"

In one study of class inclusion reasoning, an intriguing pattern was found. Children of ages 3 and 4, who could not repeat the question and clearly had not learned any rules about classes, were more likely to answer correctly than children of ages 5 and 6. Children of ages 7 and 8 performed better than any of the younger children. The 5- and 6-year-olds, who answered quickly and confidently, were consistently incorrect. They seemed unable to inhibit the more obvious comparison in order to consider the actual question (McCabe, Siegel, Spence, & Wilkinson, 1982).

Masterfile

Laura loves to sit and sort her change into piles (categories) of coins and then to see how high she can stack each type of coin.

Two processes appear to contribute to classification judgments among young children. First, perceived similarities among target objects guide judgments about whether the objects belong to the same category. Second, verbal labels play an important role in cuing children into the similarities among objects. When no verbal labels are available, children judge whether two objects are members of the same category based on the number of similar features. In comparison to adults, who rely less on verbal labels than on similarity of features, young children expect the labels to provide important information about objects, but they do not rely solely on these labels to guide their judgment (Sloutsky & Fisher, 2004).

From ages 6 to 12, children's knowledge of categories and the information associated with them expands dramatically. Moreover, children have a broad range of categories available into which to incorporate a novel observation. The capacity for classifying and categorizing has been explored in relation to specific domains, such as health and illness or concepts of the family. For example, children were told about 21 different human groupings and asked to say whether these groupings were a family: "Here are Mr. Mead and his son, Tom. They live together, just the two of them. Are they a family?" The youngest participants (4- to 6-year-olds) had trouble accepting examples involving single parents or biologically related people who did not live in the same home as instances of a family. Principles of biological relatedness and shared physical residence were both important to these children's view of a family. By middle childhood, the children were able to accept a wider variety of groups as meeting certain essential criteria of a family, usually biological relatedness and emotional closeness. Emotional closeness was endorsed by 80 percent of the participants as a defining feature of a family and was used repeatedly as a basis for judging whether a specific instance of a grouping could be considered a family or not (Newman, Roberts, & Syre, 1993).

Categorization skills can be used in an active way to construct and constrain behavior. Butler and Weatherall (2006) observed the natural use of categorization in the play sequences of 6- and 7-year-olds. Children systematically mapped participants to categories of play roles and used these categories to establish appropriate behaviors within the play sequence. The use of membership categories, such as good and bad pirates, provides a guide toward the kinds of actions, props, and strengths or vulnerabilities children are allowed within the pretense. These categories are used to include new players to the situation and to guide the initiation of new play sequences that will fit with the established categories.

Computational Skills

A third characteristic of concrete operational thought is the development of **computational skills**. The number symbols (1, 2, etc.) can provide three types of information: nominal, cardinal, and ordinal. *Nominal numbers* are used like names, such as the number on a football player's jersey or a home address. They do not refer to an amount. *Cardinal numbers* refer to a quantity (e.g., two siblings or 5 minutes). *Ordinal numbers* refer to the position or progression of things in a set (e.g., first, second, third) rather than to a specific amount. In the transition from preoperational to concrete operational thought, children shift from using numbers in a nominal way (knowing and reciting the names of numbers, or reciting their street address) to the ordinal and cardinal nature of numbers (Canobe, 2008).

Conservation of number is achieved around age 6 or 7 (Halford & Boyle, 1985). Once they have acquired the operations underlying conservation of number, children understand that certain physical transformations will not alter the number of units in a set. If 10 poker chips are lined up in a row, the number remains constant whether they are spread out, squeezed tightly together, or stacked. Children can use counting to answer a "how many" question sometime between the ages of 3 and 4. For example, they can assign one number to each item in a set of four poker chips and tell you that there are four chips in all. However, young children have more difficulty selecting a set of six chips from a larger pile, or establishing that two sets of chips are equal in number. They also have trouble solving verbal story problems when no concrete objects are present (Jordan et al., 1992; Sophian, 1998).

Young children differ widely in their mathematical knowledge and problem-solving skills. Success in doing addition and subtraction requires counting knowledge, working memory, understanding of part–whole relationships, familiarity with the language and features of specific problems and experience with a variety of strategies for estimating answers, solving problems, and checking one's answers (Canobi, Reeve, & Pattison, 2003; Ginsburg & Pappas, 2004). The ability to solve addition problems begins with an understanding that cardinal numbers refer to quantities. There is clearly a link between conservation of matter, conservation of number, and the ability to add or subtract quantities (Sophian, 2007).

Early number competence includes an understanding that each number is one more than the number preceding it and one less than the number following it. This understanding allows children to make quick and accurate judgments about the value of small quantities and to understand the logic behind joining or separating of sets (e.g., 5 and 2 makes 7; 7 take away 2 leaves 5). During the first few elementary grades, most children acquire the complementary operations of addition, subtraction, multiplication, and division and learn to apply these operations no matter what specific objects or quantities are involved. Longitudinal studies show that children's number competence and rate of growth in understanding numbers in kindergarten and first grade are strong predictors of their mathematics achievement by third grade, a point at which many children are required to take mathematics assessment tests (Canobi, 2004; Jordan, Kaplan, Ramineni, & Locuniak, 2009; Zur & Gelman, 2004).

There is a difference between the cognitive understanding of single computational operations, such as addition and subtraction, and the coordination of computational abilities to solve mathematics problems (Montague, 2006). As the problems become more complex, involving larger numbers, more numbers, or numbers embedded in story problems, same-grade children demonstrate notable differences in the speed and accuracy of their solutions. The explanation for these differences may rest with the social and cultural context of learning, especially the quality of interactions between teachers and their students. Teachers differ in their confidence about their own mathematical abilities, as well as their ability to assess children's understanding of mathematics and to select appropriate approaches to mathematics instruction. In a detailed policy report on mathematics education for young children, the researchers concluded that early childhood mathematics instruction is poor, failing to build upon the basic capacities of mathematics understanding that most children bring to the preschool or kindergarten setting. “The typical situation is that (teachers) are poorly trained to teach the subject, are afraid of it, feel it is not important to teach, and typically teach it badly or not at all,” noted Ginsburg, Lee, and Boyd (2008, p. 1). More research is needed to clarify factors that support the cognitive basis of computational skills and factors that support more advanced computational problem solving (Newcombe et al., 2009).

Central Conceptual Structures and Computational Reasoning. A group of theorists, sometimes referred to as neo-Piagetians (Morra, Gobbo, Marini, & Sheese, 2008; Young, 2011) agree with Piaget’s characterization of development as stage-like rather than continuous. They also consider biological maturation as providing the basic constraints on cognition at any given age. And they agree that children are developing internal mental structures that support logic and reasoning across problems. However, they argue that Piaget’s broad characterization of stage-related mental structures is too general—it does not take into account the evidence from neuroscience about the maturation of the brain, and it does not consider the insights and skills derived from instruction and practice that can advance children’s reasoning.

Robbie Case’s theory of central conceptual structures is an example of this neo-Piagetian perspective (Case, 1998). Case drew on evidence about changes in processing speed, memory, and executive control to explain that as children get older they can keep more information in the mind at once, thereby allowing them to organize, coordinate, and compare data in order to solve problems. Case acknowledged the role of instruction through guided teaching, expanded opportunities for exploration, and encouragement for practice. Advances in reasoning emerge as operations become more and more efficient, a result of the integration of neurological maturation, independent exploration, practice, and instruction (Case, 1987). At the same time, he observed that children did not advance in their reasoning at the same rate across specific domains. The ability to coordinate dimensions related to number did not generalize to this same ability in problems involving spatial relations or interpersonal problems.

The product of this approach was the theory of central conceptual structures (Case & Okamoto, 1996). “Central conceptual structures were originally defined as networks of semantic modes and relations that have an extremely broad (but not system-wide) domain of application and that are central to children’s functioning in that domain” (Case & Okamoto, 1996, p. 5). Through empirical study of children’s understanding of number, Case provided an example of this idea of a conceptual structure. At the age of 4 many children can count to five, and they can judge quantity when groups of items are presented to them in order to say which group has more. However, they are often incorrect in answering a question like: which is bigger, 4 or 5? In other words, the central conceptual structure that links a number word, like two or four, to an idea of a set of items with a certain quantity, has not yet emerged. By the age of about 6, children understand that giving an item a new number tag or word is the same as changing its quantity. The conceptual structure of the relationship between numbers and quantity becomes a tool that can be used in many problems involving quantity such as assessing distance, or measuring length or weight.

Case suggested that structures, such as the one described here, depend upon the maturation of certain central processing capacities, especially processing speed and short term memory storage, and the development of executive functions that support the integration of information, especially the ability to attend to and organize multiple elements. Once a central conceptual structure is formed, it provides a way of understanding a variety of situations within and across content areas. These central conceptual structures are the basic building blocks upon which more complex structures are based.

The specific conceptual structure differs from one domain to another. For example the basic understanding of the relationship of number words and quantity is a central conceptual structure for arithmetic, and may apply to other domains where measuring and counting are important. It is not the central conceptual structure for social understanding, for example that behaviors of another person may be intentional and motivated by needs and desires. Each domain has its own conceptual structure. However, the process of moving from labeling states to recognizing the link between states and then attributing causal or relational characteristics to these states is roughly the same. Thus, Case offered a model of cognitive development that is at once content specific and developmentally general suggesting a common path of development while also accounting for individual differences based on biological maturation, experience with problems in a particular domain, and practice.

Metacognition

How do children know what they know? What reasons do they give to justify or support their answers? **Metacognition** refers to a range of processes and strategies used to assess and monitor knowledge. It includes the feeling of knowing that accompanies problem solving—the ability to distinguish those answers about which we are confident from those we doubt (Tarricone, 2011). One element of this feeling of knowing is understanding the source of one’s beliefs. For example, we can be told about sand, we can see pictures of it for ourselves, or we can feel and touch it. All three of these sources of information may coincide to create a single belief, or we may discover that there are inconsistencies

Table 8.1 Components of Concrete Operational Thought

Component	New Abilities
Conservation	Ability to apply the identity operation Ability to apply the reversibility operation Ability to apply the reciprocity operation
Classification	Ability to categorize objects according to some common dimensions Ability to induce that properties of one member of a class apply to others Ability to order subclasses in a hierarchy
Computational Skills	Ability to understand that numbers represent quantities Ability to manipulate quantities using the operations of addition, subtraction, multiplication, and division

between what someone says is true and what we perceive through sight or touch. By the ages of 4 and 5, children are able to understand how all three sources of information have contributed to their understanding of an experience (O'Neill & Gopnik, 1991).

Metacognition includes the ability to review various strategies for approaching a problem in order to choose the one that is most likely to result in a solution. It includes the ability to monitor one's comprehension of the material one has just read and to select strategies for increasing one's comprehension (Currie, 1999): "I need to reread this section." "I need to underline and take notes to focus my attention on new information." "I need to talk about this with someone in order to understand it better."

Psychological mindedness is an aspect of metacognition, the ability to think about what might be accounting for one's own or another person's behavior. It requires building a link between experiences, emotions, and behaviors. For example, a child who is feeling sad may think about what happened in the recent past that is producing this feeling. This would be a type of reflection on one's psychological state (Lagattuta & Wellman, 2001).

Metacognition develops in parallel with other cognitive capacities. As children develop their ability to attend to more variables in their approach to problems, they simultaneously increase their capacity to take an executive posture in relation to cognitive tasks. They can detect uncertainty and introduce strategies to reduce it. They are increasingly able to think about what is possible and from there to select what is the best answer or the most likely alternative (Gauffroy & Barrouillet, 2011). Children can learn study techniques that will enhance their ability to organize and recall information. These capacities continue to develop as the child becomes a more sophisticated learner (Veenman, Wilhelm, & Beishuizen, 2004).

Metacognition is a natural component of cognitive development. However, just like first-level cognitive capacities, it is constructed in a social context. Interactions between children and adults or peers may nurture and stimulate metacognition by helping children identify sources of information, talk about and recognize the differences between feelings of certainty and uncertainty in their knowledge, and devise effective strategies for increasing their feelings of knowing (Stright, Neitzel, Sears, & Hoke-Sinex, 2001; Teong, 2003).

FURTHER REFLECTION: *Concrete operational thought is an approach to analyzing and solving problems. Think back to a task or activity that you were engaged in during middle childhood that required systematic problem solving. Describe the activity. Can you identify any aspects of concrete operational thought that were involved in this work? (For example, a project that involved coordinating two or three variables, using classification or categorization skills, and/or using combinatorial skills.)*

Skill Learning

OBJECTIVE 3 Analyze the nature of skill learning, and examine societal factors that provide the contexts in which skill learning occurs.

In addition to the cognitive achievement of concrete operational thought, middle childhood brings impressive growth in the acquisition of skills. **Skills** combine knowledge (knowing *about*) and practice (knowing *how*) directed toward identifying and solving significant, meaningful problems (Gardner, 1983, 2006; Kuhn, Garcia-Mila, Zohar, & Andersen, 1995). Typically, a person moves through a developmental progression within a skill area, starting off as a **novice**, becoming more proficient, and then, depending on a combination of aptitude, training, and practice, becoming an **expert.** The importance of skill development is highlighted by the United Nations declaration of July 15 as World Youth Skills Day. According to UN Secretary General Ban Ki-moon, "Skills development reduces poverty and better equips young people to find decent jobs. It triggers a process of empowerment and self-esteem that benefits everyone" (United Nations, 2016).

Cultures differ in the kinds of skills that are valued (Greenfield, Keller, Fuligni, & Maynard, 2003). In some societies, like ours, symbolic skills focusing on reading, mathematics, and abstract reasoning are highly valued. In other cultures, reading and mathematics are of less value than agricultural skills, hunting, or food preparation. In some cultures, parents consider social skills (knowing how to behave appropriately with peers and teachers), practical skills necessary for adjustment to school (completing one's homework), and motivation (working hard to understand a problem) as more important indications of intelligence than cognitive accomplishments (Neisser et al., 1996; Sternberg, 2007). In many African cultures, parents emphasize social intelligence, the ability to be attuned to the social intentions of others, and the ability to anticipate the social impact of one's actions and the actions of others. For example, in a study of the meaning of intelligence in rural Kenya, four different concepts were used: *rieko* (knowledge and skills), *luoro* (respect), *winjo* (comprehension of how to handle practical problems), and *paro* (initiative) (Sternberg, 2007, p. 149). Parents tend to view the acquisition of technical skills and academic knowledge as important primarily insofar as these skills can enhance social intelligence, social harmony, and social acceptance (Dasen, 1984; Nsamenang, 2004).

In the United States, one observes the emergence of a wide range of valued skills during middle childhood, including mathematics, science, writing, social skills, digital media skills, sports, mechanical skills, music, dance, theater, art, cooking, sewing, crafts, reading, and health-management skills. Many out-of-school programs designed for children ages 6 to 12 focus on skill development. Organizations such as 4-H, scouting, Olympics of the Mind, and Junior Guards, as well as team sports provide opportunities for children to acquire and advance their skills.

One area that is often overlooked in the focus on skill development is **health literacy**, knowing where to find trustworthy information about health concerns, understanding the information that is provided, and using the information to make informed decisions about one's health (Nemours, 2016). In a website on Kids' Health, the Nemours foundation provides information written specifically for children in middle childhood in order to foster health-related skills. Most children at this age are curious about their health and want to know how to stay healthy. They may be confused about the information they get about health, and, just as with other areas of skill development, they need opportunities to practice good health-related behaviors. Looking at the list in Table 8.2, you can appreciate the range of topics that are included and the need to foster knowledge, motivation, and behaviors that will build health-related skills and habits.

The nature and diversity of skills and the fact that children can function at high levels in some but not in others raises the question of exactly what is meant by *intelligence*. The debate about intelligence is especially relevant in middle childhood because this is when intelligence tests are administered and school placement decisions are made. As children discover the results of these tests, they make personal attributions about their ability or potential. Thus, IQ tests have a direct impact on the kind of educational experiences that children encounter and on their sense of academic self-efficacy. Three theoretical approaches to the definition of intelligence are discussed in the **Applying Theory and Research** box What Is Intelligence?

Features of Skilled Learning

Skills are actions that take place in specific contexts (Fischer & Bidell, 2006). One uses the skill of manipulating a fork for eating, not to type on a computer. Skills can be of varying levels of complexity, from whistling a tune to playing poker. In each case, they have a developmental trajectory—the skill begins in some rudimentary form of action, which may mature to increasingly high levels of performance. Skills are both context specific and culturally guided. The skill of managing a fork for eating is valued in most Western cultures; however, chopsticks are the preferred tool in many Eastern cultures.

Skills change as they become more advanced; they are also integrated with other skills that may permit new, more complex skills. Each skill is comprised of systems that must be coordinated in order for the skill to be effective. For example, the use of a fork for eating requires hand-eye-mouth coordination, judgments about the consistency and size of the food, and understanding cultural practices for eating. Once the basic skill of using a fork becomes well established, it can be integrated into more complex skills such as cutting food with a knife and a fork, or the use of a fork in food preparation. The systems that contribute to one skill, such as hand–eye coordination, may contribute to more than one skill. These contributing systems may develop at different rates, thus explaining why a skill may change slowly and then seem to advance to a new level rather suddenly.

Skills are self-organizing, goal-oriented actions designed to perform specific functions in a particular environment. As the goals or the contexts for skill performance change, the skills may be modified or integrated with other skills to produce new behavior. For example, think about playing the piano as a skill. Many components are required in order to play, including memory, auditory perception, manual dexterity, rhythm, and the ability to read music. As one area improves, the level of playing may improve so that the notes are smoother, more rhythmic, and more musical. At some point, simple tunes may be replaced by more complex compositions requiring new fingering, more complex rhythms, faster speed, and coordinated use of right and left hands. As the technical challenges of playing the piano are mastered, the person may introduce emotion, interpretation, liveliness, and a personal voice into the music. Now, the skill of playing the piano becomes a means of self-expression and possibly the entertainment of others.

Principles of Skill Development

Four principles have been identified for understanding how complex behavioral skills are achieved. First, the development of a skill depends on a combination of sensory, motor, perceptual, cognitive, linguistic, emotional, and social processes. In sports, for example, a child must learn to coordinate specific sensory information and motor activities, understand the rules of the game, be able to communicate with the coach and the other players, gain control over emotions such as fear or anger that might interfere with performance, and sustain motivation to keep trying despite errors or defeat.

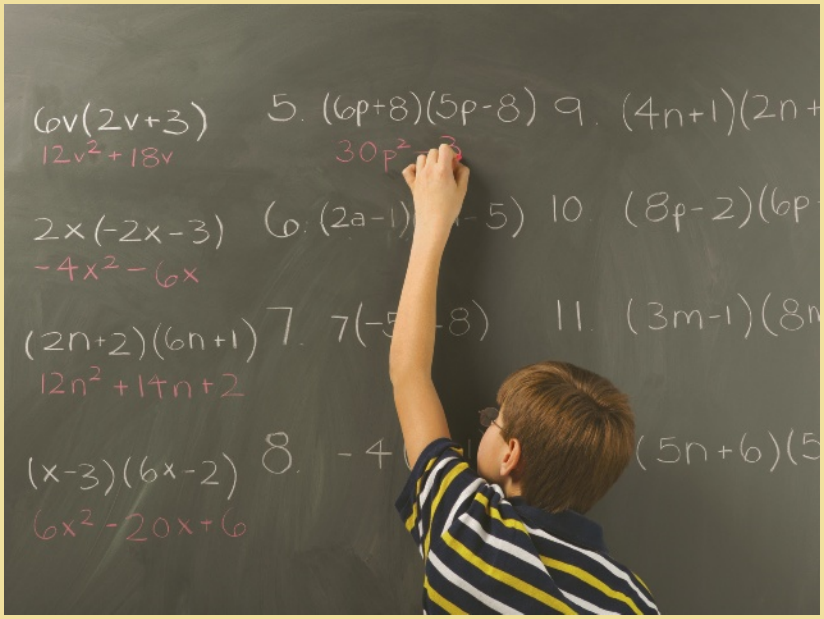
Second, skills are attained through the simultaneous integration of many levels of the component behaviors. They are not acquired in strict sequence from simple to complex. Instead, children work on the simple and more complex components of the skill at the same time. For example, as children learn the game of baseball, they practice simple skills like throwing and catching, and at the same time, they have to learn more complex skills like

APPLYING THEORY AND RESEARCH TO LIFE

What Is Intelligence?

The term intelligence is used in many contexts, with a variety of meanings. Informally, it may refer to the ability to solve difficult problems, to draw on evidence in defending an argument, or to adapt to environmental conditions. When discussing measurement, it may refer to the score on a standardized test composed of one type of item (such as *Peabody's Picture Vocabulary Test*) or many kinds of items (such as the *Stanford-Binet Intelligence Test*). Some theorists emphasize a general underlying factor, *g*, that reflects what many different types of test items have in common (Spearman, 1927). Other models suggest multiple intelligences with distinct areas of specialization. The remarkable adaptive and inventive capacities that human beings exhibit suggest a diversity of intellectual abilities, which are captured in the three theories of intelligence described here (Sternberg & Kaufman, 2011).

Jean Piaget (1972b) analyzed intelligence from a developmental perspective. His theory focuses on the logical and analytic aspects of intelligence as they arise from infancy through adolescence. He described four types of intelligence, each emerging at a different period of life: (1) *sensorimotor intelligence* (the ability to know through direct observation and manipulation of objects), (2) *representational intelligence* (the ability to distinguish between the real and the pretend, and to think about and represent objects and events that are not present), (3) *concrete operational intelligence* (the ability to detect the logical relationships among objects, to place objects in sequences, and to comprehend and manipulate numbers), and (4) *formal operational intelligence* (the ability to use experimental techniques and hypothetical reasoning to solve problems, to generalize observations from one situation to another, and to relate cause and effect in complex, multidimensional problems). These approaches to problem solving are not lost as one moves from stage to stage. Rather, each is integrated into the next level, with lower levels of reasoning being viewed as inadequate as the person achieves new capacities.



Jeffrey Coolidge/The Image Bank/Getty Images

Alan is solving mathematical problems involving unknowns. Piaget would consider this the beginning of formal operational thinking. Gardner would call it logical-mathematical intelligence, and Sternberg would call it analytic intelligence. What is its practical or adaptive value for Alan's future?

Howard Gardner's (1983, 2006; Davis, Christodoulou, Seider, & Gardner, 2011) theory of multiple intelligences identifies at least eight distinct intelligences, each with its own content and unique contribution to solving important, meaningful problems. These include *linguistic*, *musical*, *logical-mathematical*, *spatial*, *naturalist*, *bodily-kinesthetic*, and two forms of personal intelligence—one directed toward understanding one's own internal feelings (*intrapersonal*) and the other directed toward identifying and differentiating among the characteristics of others (*interpersonal*). This theory recognizes domains of human functioning that show evidence of high levels of achievement, not all of which are related to scientific, mathematical, or verbal reasoning. They cover a broader range of skills than are normally included in tests of intelligence, validating the variety of individual differences in competence typically observed among school-age children (Gardner, Kornhaber, & Wake, 1996).

A third view, devised by Robert Sternberg (1985; Sternberg, Castejon, Prieto, Hautamäki, & Grigorenko, 2001), described three universal processes of intelligence that are expressed in three different abilities—analytic, creative, and practical. The universal processes include: (1) executive processes including the ability to make a plan to achieve a goal, monitor progress toward the goal, and evaluate and/or modify the progress and plan; (2) performance components, which refer to the ability to carry out the steps indicated by the executive processes; and (3) knowledge components, which include the ability to the gather the information needed or the skills required to implement the plan (Education Encyclopedia, 2016). These processes can be exercised in each of the three domains: analytic, creative, or practical intelligence. Analytic intelligence usually involves evaluating information, comparing and contrasting alternatives, and applying principles of logic. This type of intelligence is systematically measured by tests of intelligence and is the primary focus of formal classroom teaching. Creative intelligence is a bit harder to define because it may be expressed differently in different fields such as writing, art, science, and music. Typically,

APPLYING THEORY AND RESEARCH TO LIFE (continued)

Alexey Fursov/Shutterstock.com

By the age of 6, Kim has already reached a very high level of bodily-kinesthetic intelligence in rhythmic gymnastics. As Gardner points out, intelligence can be evidenced in many different domains including music, drama, art, sports, mathematics, and invention.

creative intelligence involves producing a novel or unusual solution, often bringing together information or skills from diverse domains to address a situation in a new or unexpected way. Practical intelligence is knowledge about how to do something, how to assess a situation, and how to get a desired outcome. In his theory of successful intelligence, Sternberg strives to explain how the person integrates mental capacities and life experiences with the demands of the culture in order to achieve an effective adaptation with the environment (Sternberg, 2012).

Cultures differ in how they define intelligence, and the knowledge and skills required to be successfully intelligent (Sternberg, 2014). For example, some groups value social competence highly, recognizing that intelligence involves knowing how to maintain positive and cooperative group relations. In these cultures, intelligence is demonstrated by being able to interact effectively with people in various positions of authority and showing the proper respect in social contexts. Other cultural groups emphasize cognitive skills, especially those skills that will result in good grades in school. A third cultural perspective might focus on a moral view of intelligence, that is, doing what is right and showing humility without judgment of others. The nature of intelligence and its key features are culturally constructed and passed along from teachers to students and from parents to their children (Castles, 2012; Sternberg, 2004).

Critical Thinking

1. Compare the three theories of Piaget, Gardner, and Sternberg. What, if anything, do they have in common? What are their distinguishing features?
2. Contrast the implications of the three theories of intelligence for educational practice. How might teachers approach the teaching/learning process differently depending on which of these three views of intelligence they endorse?
3. Many scholars support the idea of a single underlying factor, often referred to as *g*, which refers to basic intelligence. Do you think there is such a thing as *g*? Summarize the evidence you have for your belief. How does the idea of *g* fit with the three theories presented here?
4. Explain the view that intelligence is culturally constructed. Do you believe there can be such a thing as a culture-free test of intelligence? Why or why not?

fielding a ground ball and throwing it accurately to the first baseman in order to make an out.

Third, the limits of the human system place constraints on an individual's capacity to perform skilled behavior. With practice, lower level processes begin to function automatically, so a person can attend to higher order processes. In writing, for example, young children struggle with the physical act of printing and writing, concentrating largely on the motor skills necessary to make each letter, word, and sentence. A skilled writer can write with little effort, focusing attention on the meaning of the writing, the plot, or the character development rather than on the physical aspects of the task.

Fourth, skilled behavior requires the use of strategies. Skillful people operate with purpose and continuously monitor their performance. They perceive breakdowns in performance, are selective in focusing attention on various aspects of what they are working on, and refine higher order processes as they perform the skill. This model of skill development focuses on the elements that are necessary in order to move from what might be considered a novice level to a more advanced level in skill performance.

Early Deprivation and Skill Development

Studies of children who have experienced early and prolonged deprivation, for example children who have spent 12 months or more in institutional care before adoption, show evidence of neurological deficits in certain areas by the age of 8 or 9. For example, the children who experienced prolonged institutionalization perform less well on tests of visual memory, attention, and inhibitory control, but about the same as children who were adopted before 8 months and those who were never institutionalized on tests of auditory memory or executive function (Pollack et al., 2010).

The impact of early deprivation may be masked in the early years, when expectations for skill development are at a novice level. However, by age 8 or 9, these neurological deficits may have a more noticeable impact on a child's ability to reach advanced, sustained levels of competence or mastery. Children who are placed in foster care at an early age and who continue to reside with the same family appear to benefit the most from early intervention, and their cognitive abilities show the greatest degree of resilience (Fox, Almas, Degnan, Nelson, & Zeanah, 2011).

In each distinct area of skill development, a combination of maturational factors, aptitude or talent, opportunities for exposure and training, and the value placed on the skill by the family, school, or larger society all play a role in how rapidly and how well a skill will be developed. The **Human Development and Diversity** box presents a cross-national comparison of mathematics mastery, highlighting patterns of performance in the United States, Japan, and Taiwan. Given the societal emphasis on encouraging students to enter the STEM fields (science, technology, engineering, and mathematics), mathematics skills are essential to pursue this path.

In the sections that follow, we look at reading as a specific case of skill development and at the social and cultural contexts within which reading emerges. Whereas certain cognitive abilities are foundational in both math and reading, reading appears to be essential for initial competence in mathematics. At more advanced levels, however, each of these skill areas requires its own foundation of conceptual structures and opportunities for practice.

Reading

Reading may be the most significant skill that develops for children in the United States because it opens the door to all the others. **Literacy** transforms children, just as the advent of the written alphabet transformed civilization. Reading provides access to new information, new uses of language, and new forms of thinking. Children are limited in their ability to learn mathematics, social studies, and science if they cannot read. However, once they can read fluently, the possibilities for independent inquiry expand significantly.

Reading builds on language. Gradually children begin to appreciate the link between spoken words and their written or printed counterparts. Children begin to read in a variety of ways. Some children memorize the words they see in books or signs and repeat them. Some children begin to read by learning letters and the sounds linked to them and by experimenting with sounding out the letters when they are strung together. The bridge between spoken language and the written word requires experience with books as well as some types of instruction. Gradually, through a process of trial, feedback, and repetition, children learn to read simple words and sentences (Knight & Fischer, 1992; Rayner, Schotter, Masson, Potter, & Treiman, 2016). At some point, a child begins to articulate the concept "I can read" or "I am a reader." Once this idea is part of the self-concept, efforts to read increase and are energized by a confidence in one's potential for success.

Reading is a visual, cognitive, and social process that improves greatly with practice. In order to read, children have to perceive the printed marks that comprise letters and words with accuracy. They have to fixate on words and move their eyes along the lines and paragraphs to capture sentences. As this is happening, the reader has to recognize and recall the meaning of words before moving along. The recognition process is linked to the child's vocabulary and to the frequency with which the child has seen the word before. Thus, basic executive functions of attention, working memory, and flexibility are linked with visual processes and language competence to achieve reading skills (Cantin et al., 2016; Rayner et al., 2016).

Young children may have a large spoken or oral vocabulary. They understand the meaning of many words. However, in order to read, they have to realize that each spoken word is comprised of sounds that are represented in English by letters or letter combinations. **Phonemic awareness**, that is, knowing the sound of a letter and being able to hear it as one reads, is a key to reading. Children with **dyslexia** frequently have trouble with this process of connecting letters and their sounds. Another component of reading is the rapid naming of objects, referred to in the literature as RAN (rapid automatized naming). To measure RAN, children are asked to name 40 items including colors, objects, numbers, and letters as fast as possible. RAN, measured before children have begun formal reading instruction, is a predictor of reading fluency. Scholars who study reading argue that RAN is a general capacity for object recognition, not only letters but also numbers and other symbols, that contributes to the reading process; as a child learns to read the brain treats printed words as if they are objects to be recognized (Fuchs, Geary, Fuchs, Compton, & Hamlett, 2016; Lervåg & Hulme, 2009).

Reading involves more than recognizing one word at a time. **Reading fluency** refers to the accuracy and speed with which children can read words in a text. Children who struggle with figuring out each word may find it difficult to capture the meaning of a sentence or paragraph. Being a slow reader may be related to having a limited vocabulary, difficulties in attention, limited recognition or memory retrieval for words previously encountered, and limits in perceptual span (e.g. the amount of information captured in a single fixation on a line of text) (Sperlich, Meixner, & Laubrock , 2016). Over time, children who have difficulty reading are less willing to practice reading outside of class, and this lack of practice confounds their problems with fluency (Gabrieli, 2009). Certain interventions have been shown to be successful for children who are having difficulties with reading, especially when these interventions occur early in kindergarten or first grade and involve intensive, small group lessons with active, engaging interactions between students and their teachers (Cirino, Vaughn et al., 2009).

Parents Influence Their Child's Reading Abilities.

Parents affect their children's reading in at least six ways (Tudge, Putnam, & Valsiner, 1996).

1. The value they place on literacy
2. The emphasis they place on academic achievement
3. The reading materials they make available at home
4. The time they spend reading with their children and listening to their children read
5. The way they read with their children
6. The opportunities they provide for verbal interaction in the home

HUMAN DEVELOPMENT AND DIVERSITY

Cross-national Comparisons of Mathematics Ability

In 1980, comparative studies showed that first and fifth grade children in Minneapolis, Minnesota, were substantially behind their age-mates in Sendai, Japan, and Taipei, Taiwan, in tests of mathematics achievement. In a 10-year follow-up, U.S. children still lagged behind, and by the 11th grade, the gap in achievement had widened (Stevenson, 1992; Stevenson, Chen, & Lee, 1993). Even the top 10 percent of the Minneapolis students scored at about the average level of the Taipei and Sendai students.

Beginning in 1995, and repeatedly to 2011, the U.S. National Center for Education Statistics sponsored the Trends in International Mathematics and Science Study (TIMSS), which examined mathematics and science teaching practices and student accomplishment for grades 4 and 8. The project involves 63 countries and other education systems (states and provinces). Analysis of the 2011 data indicated significant improvement in U.S. students' scores from 1995Nonetheless, the following non-U.S. educational systems had scores that were above the U.S. average in mathematics: Taiwan, Korea, Singapore, Hong Kong, Japan, the Russian Federation, and Quebec, Canada (Provasnik et al., 2012). Mathematics scores were grouped into four categories: low, intermediate, high, and advanced. In 2011, 7 percent of U.S. eighth grade students scored in the advanced level. Seven countries had significantly higher percentages of students scoring at this advanced level, led by 49 percent of students in Taipei, China.

Think about mathematics from an ecological systems perspective. At least five sociocultural factors interact to contribute to the advantages that Japanese and Chinese children show in comparison to U.S. children in mathematical skill development: (1) cultural beliefs and values placed on academic success; (2) the school resources available to children; (3) parents' beliefs and strategies that encourage or support mathematics achievement (4) teachers' preparation, training, and approach to teaching mathematics; and (5) the peer culture that rewards school achievement.

1. *Culture*. There are cultural differences in beliefs about academic achievement that impact how parents and teachers approach the process of learning. U.S. parents and teachers highlight the importance of natural ability as a major factor in accounting for individual differences in mathematical ability. In contrast, Japanese and Chinese parents and teachers are more likely to see academic achievement as a result of studying hard. If you believe that math or science achievement depends on natural ability, you might conclude that not much can be done to improve performance. If you believe that math and science skill depends on effort, you may be more inclined to devote additional time and focused application to reach a new level of performance. Other comparisons suggest that Chinese parents emphasize their child's academic failures, encouraging children to strive to improve by paying special attention to their mistakes. U.S. parents emphasize their child's successes, hoping to bolster their self-esteem by pointing out how well they are doing (Ng, Pomerantz, & Lam, 2007).
2. *Resources*. School resources, which impact the number of teachers per student, the salaries for teachers, the availability of teaching materials, and the quality of the physical environment, are all associated with academic achievement. In the U.S., living in a poor community has a substantially negative impact on student achievement in comparison to other countries where health and educational resources are available to all children regardless of their family's income (Balfanz & Byrnes, 2006; Tucker-Drob & Bates, 2015).
3. *Parents' expectations about schools*. Parents differ in their views about what they should expect of their children and their children's schools. U.S. parents appear to be satisfied with their children's level of mathematics performance and do not expect their children to do better. In contrast, Japanese and Chinese parents have high expectations for their children's performance. Parents differ in how they evaluate their children's schools. U.S. parents are generally satisfied with the school curriculum and think that the schools are doing a good job. Far fewer Japanese and Chinese parents view the schools as good or excellent. The public

christian kober/Alamy Stock Photo

Japanese mathematics classes involve two teachers, one who gives instruction to the whole class, and one who meets individually with students to help them in areas where they may be having difficulties. In this way, all the students are able to move ahead at the same pace and "no child is left behind."

pressure in these cultures is for greater improvement in the quality of education. Even though Japanese and Chinese children spend more time on homework than do U.S. children, their parents are more likely to encourage them to spend even more time on homework.

4. *Teachers*. Teachers' specialized preparation to teach mathematics and confidence in their ability to teach mathematics, as well as their satisfaction with their teaching assignments and work environment are all associated with students' mathematics achievement (Ker, 2016; Marcenaro-Gutierrez, Luque, & Lopez-Agudo, 2015). There are also notable differences in the approach to mathematics instruction across countries. In Japan, for example, the classroom teaching approach is quite distinct from that in the United States. Based on videotapes of U.S. and Japanese classrooms, one can observe Japanese teachers spending less time reviewing and more time presenting new content; more time focusing on complex problems that require four or more steps to reach a solution; and more time on problems that require connections among mathematically related concepts rather than a repetition of the previous problem (National Center for Education Statistics 2015a). If you are interested in viewing examples of classroom teaching of math and science across countries, you can find sample lessons at the TIMSS video website.
5. *Peers*. Mathematics achievement is enhanced when students are embedded in a peer culture that rewards academic achievement and working hard at school. Having friends who do well in mathematics can help advance a child's mathematics ability. In contrast, being part of a peer group that is disengaged from school can undermine a child's academic goals and reduce their willingness to spend time on challenging mathematics homework. The academic and career aspirations of the friendship group can greatly impact a child's motivation and interest in math (DeLay, Laursen, Kiuru, Poikkeus, Aunola, & Nurmi, 2015; Sebanc, Guimond, & Lutgen, 2016).

Critical Thinking Questions

1. Describe your experiences in mathematics and science instruction in elementary and secondary school. Did you leave high school feeling confident about your ability in these domains? What role did teachers, parents, and peers play in your interest and achievement in mathematics and science?
2. Analyze the distinctions among the U.S., Japanese, and Chinese cultures that you believe make the greatest difference with respect to science and mathematics achievement. Hypothesize about how the concepts of individualism and collectivism influence the teaching and learning process.
3. Assess whether differences in mathematics and science achievement are a result of differences in basic ability or differences in motivation and effort. Support your view.

There are different ways to approach the social occasion of reading. Some parents ask their children about the story as they read along to make sure the child understands. Some try to expand on the story, talking with their children about other things they notice in the pictures or experiences related to the story. Some parents point out words and specifically teach about the sounds of letters as they read (Justice & Ezell, 2000; Reese & Cox, 1999).

In a study of parents' contributions to their children's literacy development in the United States and Japan, family members in both countries were found to employ a range of strategies to encourage their children's ability to read. These included reading and telling stories, discussing stories, teaching vocabulary, writing about their experiences, playing board games, and watching certain types of television programs (Saracho & Shirakawa, 2004). Parents who value the ability to read do some direct teaching to promote reading, urge their children to do well in school, provide resources for reading, take turns reading and listening to their children read, and talk with them about what they are reading. All these strategies produce children who are more skilled readers (Bus, van IJzendoorn, & Pellegrini, 1995; Haney & Hill, 2004).

Parents also have an indirect effect on how well a child will learn to read by influencing the child's placement in a school reading group. Ability grouping for reading instruction is practically universal in elementary schools. Teachers depend on their perceptions of a child's ability, work habits, and behavior when they assign students to reading groups. The higher the level of the children's reading group, the better they learn how to read. Parents need to understand the school's approach to ability grouping and help their child understand it (National Association of School Psychologists, 2002). Parents who encourage good work habits and appropriate classroom behavior are likely to influence a teacher's perception of their child and, as a result, influence the child's assignment to a more advanced reading-level group.

The Social and Cultural Contexts of Reading. The analysis of reading provides many good examples of the importance of context. First, societies differ in their level of literacy. For example, in Afghanistan, a country of over 32.5 million people, 52 percent of men and 24 percent of women age 15 and older are literate. In Israel, a country of over 8 million, 99 percent of men and 98 percent of women are literate (Central Intelligence Agency, 2016). Expectations on how much children should be read to, when they should be able to read, and the level of skill development they are expected to reach at a certain age depend on cultural norms for literacy. The Progress in International Reading Literacy Study (PIRLS, 2011) assessed reading activities of fourth graders in 45 countries. In addition to assessing reading competence for literary and informational purposes, the study examined students' enjoyment of reading. There is a clear bi-directional relationship between reading

Blend Images/Superstock

Children who enjoy reading books outside of school show the greatest gains in reading achievement between second and fifth grades.

ability and "reading for fun." Students who are better readers enjoy reading more, and students who enjoy reading become better readers. In the United States, 27 percent of the students reported that they liked reading; this includes enjoying reading, reading for fun daily or almost every day, and enjoying talking with others about what they read. In 23 countries, a larger percentage of fourth graders reported that they liked reading than was the case in the United States (Mullis, Martin, Foy, & Drucker, 2012).

Second, the purpose of literacy varies from one culture to the next. For example, missionaries introduced literacy to the Kaluli of New Guinea primarily as a way to teach the Bible. Among the Kaluli, reading is viewed as having limited purpose for daily life and as too difficult for children (Schieffelin & Cochran-Smith, 1984). In many societies, the ability to read the Bible, the Koran, or the Torah is the principal reason for literacy, and that one book is the primary written resource.

Third, the mark of a literate person varies by context. In the United States, we have age-graded expectations for reading achievement and tests to measure reading ability. By the time they are applying to college, students are expected to be able to analyze a complex text for meaning, know advanced principles of grammar, write a well-organized essay under time constraints, use approved strategies for citing references, and understand principles of fair use and plagiarism. However, in the digital environment reading and writing follow other standards. Some environments, such as texting and Twitter, encourage the use of brief messages and replies. Online texting often integrates words, emoticons, symbols, abbreviations, and acronyms. At the same time, children can access a vast array of online sources. To take advantage of these resources requires skills in searching as well as reading and evaluating information. With the easy sharing of digital content, the written word can be read by a wide network of "friends" who can comment and respond, creating a social environment in which reading is a skill that can be used for peer group integration or exclusion.

In more traditional societies, a good reader might be someone who can read a letter for someone else, someone who can keep track of business accounts, or someone who can accurately make a copy of a text. The point is that the achievement of literacy is a product of cultural expectations, individual capacity, and opportunities to learn (Tudge, Putnam, & Valsiner, 1996).

The emphasis on skill building and the energy that children bring to the acquisition of new skills suggest a strong parallel to toddlerhood. At both stages, children's motives for competence and mastery are directed outward to the environment. At both stages, most children delight in the potential for learning that almost every new encounter offers. However, as a result of children's cognitive capacities and their awareness of social expectations, skill learning during middle childhood is embedded in a much more complex framework of continuous monitoring and self-assessment. Children's beliefs and attitudes about which skills are important, what they should expect of themselves, what others expect of them, and what kinds of competing demands should influence their dedication to skill development all contribute to the levels of performance they are likely to achieve.

FURTHER REFLECTION: *Make a list of 15 to 20 skills that might be developed during middle childhood. Now create three lists: one for success in school, one for success in peer relationships, and one for life satisfaction and well-being after high school. Rank-order the skills from most to least important in each list. How much overlap is there in the three lists? To what extent do we need different skills to achieve different goals?*

Self-Evaluation

OBJECTIVE 4 Outline the factors that contribute to self-evaluation, including feelings of pride, self-efficacy, and ways that social expectations of parents, teachers, and peers contribute to a child's self-evaluation.

During middle childhood, the emphasis on skill building is accompanied by a new focus on **self-evaluation**. Children strive to match their achievements to internalized goals and external standards. Simultaneously, they receive feedback from others about the quality of their performance. Some children may be asked to sit at one table to receive help; others may be told to go down the hall for tutoring. Some children are designated as peer tutors who assist their classmates. These and many other signs are sources of social evaluation that children incorporate into their own self-evaluations.

In middle childhood, the peer group joins the adult world as a source of social comparison, criticism, and approval. Toddlers and early-school-age children are likely to observe and imitate their peers in order to learn new strategies for approaching a task, or out of curiosity to see how their peers are doing a particular project. But in middle childhood, pressures toward conformity, competition, and the need for peer approval feed into the self-evaluation process. Children pay attention to the work of others in order to assess their own abilities. Their athletic skills, intellectual abilities, and artistic talents are no longer matters to which only teachers and parents respond. Peers also identify others' skills and begin to generate profiles of one another: "Oh, Rafael is good in math, but he's not much at sports"; "Jane is kind of fat, but she writes great stories"; "I like Rashidah best, because she's good at everything." Depending on their resolution of the psychosocial crises of toddlerhood and early school age, children approach the process of self-evaluation from a framework of either self-confidence or self-doubt. They may expect to find tasks easy to accomplish and approach them vigorously, or they may anticipate failure and approach tasks with hesitation.

Evaluation of competence is not the same as global self-esteem. In research involving children ages 8 to 13, Susan Harter (1982, 1993) devised a method for assessing children's perceptions of competence in five specific domains that are relevant for children in this age range: scholastic competence, athletic competence, likability by peers, physical appearance, and behavioral conduct. She also measured general or global self-esteem. Her research was guided by the idea that by the age of 8, children not only differentiate specific areas of competence but also view certain areas as more important than others. She found that self-esteem is highest in those children who view themselves as competent in domains that they judge to be important. Competence in relatively unimportant domains is not strongly related to overall self-esteem.

Feelings of Pride

Feelings of pride are typically associated with positive self-evaluations. In general, children as well as adults feel happy when they succeed at an achievement-related task. However, the experience of **pride** depends in part on the child's perceptions about the cause of their success. As children mature, their feelings of pride after a success become increasingly linked to whether they attribute the success to internal factors such as their own ability or effort as compared to external factors such as the poor preparation of the other children or a teacher who is an easy grader (Graham & Weiner, 1986). In experimental tests of these relationships, young children ages 5 and 6 felt about the same degree of pride whether the success was due to internal or external factors. However, by ages 8 to 10 children were making a clearer distinction. They felt greater pride when success was due to internal factors and less pride when success was due to external factors (Graham & Weiner, 1991). By middle childhood, children are engaged in a process of self-evaluation that includes several sources of information including their past performance, task difficulty, the reactions of others, and their assessment of their ability and effort.

Self-evaluation takes place in relation to internal frames of reference, as children compare how well they can perform in one domain versus another, or how well they performed in the current situation as compared to their past performances. The internal frame of reference includes an assessment of both ability and effort. Self-evaluation also takes place in relation to external frames of reference as children evaluate their performance in light of parent, teacher, or peer feedback and observations of the performance of others (Skaalvik & Skaalvik, 2004). In the sections that follow, we focus on two different paths toward self-evaluation: *self-efficacy*, which reflects a child's personal judgment of ability, and *social expectations*, which reflect the impact of the expectations of others on a child's performance.

Self-Efficacy

How do children assess their competence in a specific ability area? Albert Bandura (1982) theorized that judgments of self-efficacy are crucial to understanding this process. **Self-efficacy** is defined as the person's sense of confidence that he or she can perform the behaviors demanded in a specific situation. Expectations of efficacy vary with the specific ability. In other words, a child may view efficacy in one way in a situation requiring mathematical ability and in another way when the situation requires physical strength.

Bandura theorized that four sources of information contribute to judgments of self-efficacy (see FIGURE 8.2 ▶). The first source is **enactive attainments**, or prior experiences of mastery in the kinds of tasks that are being confronted. Children's general assessment of their ability in any area (e.g., mathematics, writing, or gymnastics) is based on their past accomplishments in that area. There is a bidirectional relationship between achievement in a domain and one's confidence about being able to perform well in that domain. High confidence will lead to better performance, and better performance will increase one's confidence. Over time, children establish a more stable view of areas where they expect to do well and areas where they anticipate greater difficulty (Denissen, Zarrett, & Eccles, 2007). Success experiences increase self-efficacy, whereas repeated failures diminish it. Failure experiences are especially detrimental when they occur early in the process of trying to master a task. Many boys and

girls are diverted from mastering such sports as tennis and baseball because they have made mistakes early in their participation. They develop doubts about their abilities, which then prevent them from persisting in the task.

The second source of information is **vicarious experience.** Seeing a person similar to oneself perform a task successfully may raise one's sense of self-efficacy; seeing a person similar to oneself fail at a task may lower it.

Verbal persuasion is the third source. In a supportive environment, children are encouraged to believe in themselves and to try new tasks with confidence. This type of motivational talk is likely to be most effective with children who already have confidence in their abilities, and it helps boost their performance level.

The fourth source is **physical state**. People monitor their body states in making judgments about whether they can do well or not. When children feel too anxious or frightened, they are likely to anticipate failure. In contrast, children who are excited and interested but not overly tense are more likely to perceive themselves as capable of succeeding. With mindfulness training, children can learn to be more attuned to their internal state. They can acquire strategies such as slow, deep breathing, progressive relaxation, or concentrating on a calming image to reduce anxiety and focus their attention on the task at hand.

Self-efficacy judgments are related to children's perceptions of their likelihood of success. These judgments also determine the factors to which children attribute their success or failure. In the face of difficulty or failure, children who have confidence in their abilities and high self-efficacy will work harder to master challenges. They will attribute their difficulties to not trying hard enough, and they will redouble their efforts to do well. Children who have a low sense of self-efficacy tend to give up in the face of difficulty because they attribute their failure to a basic lack of ability. The level of self-efficacy also affects how children prepare to handle new challenges. In their thoughts, emotions, and preparation for action, those who are preoccupied by self-doubts differ from those who believe in themselves (Bandura & Schunck, 1981; McAuley, Duncan, & McElroy, 1989; Pajares, 1996).

Children with high levels of self-efficacy related to academic achievement are likely to set challenging goals for themselves. They are also likely to regulate their learning behaviors by deliberately enlisting a number of strategies, including concentrating, organizing their work, finding a good place to study, taking notes in class, and completing their homework assignments so that they have the best chances of reaching their goals (Bandura, Barbaranelli, Caprara, & Pastorelli, 1996; Zimmerman, Bandura, & Martinez-Pons, 1992). The following case study of Becca illustrates the behaviors and thoughts of a middle school student whose sense of self-efficacy has been declining.

— CASE STUDY Becca —

Becca, an eighth grader, is disengaging from school.

Under the weight of her family burdens, Becca's academic confidence has begun to falter. . . . In sixth grade, Becca was an A student; at the end of seventh grade, she asked to be removed from the advanced math class; and by the middle of eighth grade, her grades in all of her classes were drifting to low Cs.

A quiet girl, Becca says she has never spoken much in class ("unless I'm really, really sure of an answer, and sometimes not even then"), but with her self-esteem flagging, she stops volunteering entirely. She even begins to see her silence as an advantage: As long as she's perceived as shy, her teachers won't notice that she has, in truth, disengaged from school. . . . In a sense, Becca is invisible. Her teachers don't see her as someone in need of counseling or special help because, although her grades have dropped, she is never combustible: She never, for instance, yells in class, pounds desks, fights with other children, or conspicuously challenges authority. Becca's is a passive resistance—a typically feminine resistance. By opting out rather than acting out, Becca still conforms to the image of the ideal female student—quiet, compliant, obedient; as such she is easily overlooked, or seen as making choices rather than expressing psychological distress. "Becca is so quiet," her math teacher admits, "she gets lost in the crowd. I don't like that to happen, but it has happened with her. She doesn't disrupt. She always looks like she's paying attention, but maybe she's not. I don't know."

"Maybe she thinks she'll be more cool as a C student," her history teacher says. "But she doesn't even get it together after she gets the bad grade. I'll say, 'Becca, you have a D, you may fail,' but then she doesn't turn in the next homework assignment, which is really easy. But I think of her as someone who's responsible for her own grade, and I let her be responsible for that."

Source: Orenstein, 1994, pp. 80–81.

CASE ANALYSIS Using What You Know

1. Describe Becca's sense of academic self-efficacy.
2. Apply Bandura's model, explaining how the four factors of enactive attainments, vicarious experiences, verbal persuasion, and physical states contribute to Becca's self-efficacy.
3. How does the case illustrate the relationship of gender and school engagement? In what ways is Becca's situation made possible because of gender stereotypes?
4. Propose ways that teachers might intervene to reverse Becca's decline in academic performance and school engagement.
5. Infer likely outcomes for Becca if this pattern of disengagement continues.

Social Expectations

In middle childhood, the appraisals and expectations of significant others become incorporated into one's own self-concept and become a source for self-evaluation (Chen, Boucher, & Tapias, 2006). Self-esteem is based on the general positive regard and approval of others and on the specific expectations they have for one's ability and achievement in certain areas of performance (Harter, 2012). In attempting to assess their own abilities, children rely on many external sources of evaluation, including school grades, teachers' comments, and parent and peer evaluations (Hergovich, Sirsch, & Felinger, 2002). If feedback from important adults suggests to children that they are cooperative, intelligent, and creative, these attributes are likely to be incorporated into their self-evaluations. Children who see themselves as cooperative and intelligent are likely to approach social and intellectual tasks with optimistic expectations about their performance. Conversely, feedback suggesting lack of cooperation, intelligence, or creativity can produce a pessimistic or antagonistic approach to the challenges of skill development. Thinking back to the concept of verbal persuasion, you can see that one's judgments of self-efficacy in a particular domain can be influenced by how a relevant person has evaluated one's performance in the past.

Repeated failure information or remarks that imply lack of ability tend to make children less confident of success in subsequent tasks. This pattern of expectations appears to crystallize during grades 2 and 3. Preschoolers do not make systematic use of success or failure feedback in predicting their next success. Even in the first grade, children's expectations about the grades they will receive on their first report cards are not clearly related to their IQs or to parents' or teachers' expectations, nor are they closely related to the children's later estimates of their grades. By the end of the first grade, however, children begin to be more accurate predictors of their performance. A combination of a parent's support for the child's schooling and the child's own motivation and temperament contribute to an orientation toward schooling in first grade that impacts school achievement. School performance in first grade has been found to predict educational attainment into late adolescence and occupational attainment into early adulthood, suggesting the formation of an early and persistent view of the self as someone who can or cannot do well in school (Entwisle, Alexander, & Olson, 2005a; Alexander, Entwisle, & Olson, 2014). By middle childhood, children are clearly aware of their teachers' expectations for their performance and are likely to mirror those expectations in their own attitudes about school, academic achievement, and school behaviors (Alexander, Entwisle, & Kabbani, 2001; Weinstein et al., 1987).

Teachers' Expectations: The Self-Fulfilling Prophecy. The feedback that students receive from their teachers is not wholly objective. Teachers' expectations about their students' abilities may be based on objective assessments, but they may also be derived from stereotypes about certain types of children or from biases based on prior experiences, such as having a child's older siblings in class in prior years or hearing favorable or unfavorable comments from other teachers. Merton (1948) suggested that problems may arise through a process that he called the **self-fulfilling prophecy**. This concept refers to the idea that false or inaccurate beliefs can produce a personal reality that corresponds with them.

In the original study on the effect of teacher expectations on student performance, teachers were led to believe that certain students were late bloomers who would show major gains in IQ later on in the school year. These children, chosen at random from among first and second graders, actually did show increases in IQ of 10 to 15 points by the end of the school year in comparison to the control group (Rosenthal & Jacobson, 1968).

Subsequent studies of the self-fulfilling prophecy in classroom settings have shown that it has a consistent but comparatively small effect on student performance (Rosenthal, 1994, 1995). In one longitudinal study, students' math achievement and mathematics self-concept data were collected at the end of fifth grade, early in sixth grade, and at the beginning of seventh grade. Teachers' expectations about student performance were assessed early in sixth grade as well. Both student achievement at the end of fifth grade and teachers' expectations in sixth grade were predictive of students' achievement at the beginning of seventh grade. Researchers found that the self-fulfilling prophecy (the impact of teacher expectations separate from prior student achievement scores) was observable only for those students who were in the low achievement group. Both overestimates and underestimates of these students' abilities in sixth grade were predictive of the students' achievement in seventh grade. There was some tendency for overestimates to have a greater impact in boosting these students' performance than for underestimates to depress the students' performance (Madon, Jussim, & Eccles, 1997).

In a review of many studies that have attempted to examine the impact of self-fulfilling prophecies, the authors conclude that the impact of erroneous expectations is typically small. These incorrect expectations seem to have the most impact when children are starting a new school setting, like the start of elementary school or middle school. Evidence about whether the impact of erroneous expectations is positive or negative is mixed. Most studies find that erroneous expectations have the greatest influence when positive expectations are focused on children who are typically low-performing (Jussim, Robustelli, & Cain, 2009).

Teachers' Attributions of Ability and Effort. Teachers' expectations for a student's performance are influenced by their assessments of both the student's ability and effort. Teachers often reward what they perceive as greater effort with higher grades. It is important to appreciate that this judgement about effort may be subjective and open to bias or error (Jussim, Robustelli, & Cain, 2009). Studies of teachers' explanations for their students' math performance have noted an attributional gender bias. Teachers tend to believe that boys are somewhat more talented in math than girls. What is more, they are likely to attribute boys' successes in math to ability and girls' successes to effort. In contrast, they are likely to attribute boys' failures to lack of effort, and girls' failures to lack of ability. These attributions can be conveyed to students through subtle messages of encouragement or frustration, especially in response to students whom teachers perceive as not working up to their ability or not putting in the effort needed to do well (Espinoza, Arêas da Luz Fontes, & Arms-Chavez, 2014; Tiedemann, 2002).

Certain conditions make children more or less vulnerable to internalizing false expectations. Children who are unsure about their abilities and children who are learning something for the first time may be more likely to rely on the information they receive from others to assess their abilities. Being in a new situation, like moving to a new school or changing from elementary to middle school, may increase a child's dependence on social expectations for performance. In middle childhood, when many new domains of skill development are first being introduced, children may be more vulnerable to the effects of biased perceptions and erroneous expectations than are older children (Jussim, 1990).

Parents' Expectations. Parents' as well as teachers' expectations influence children's perceptions of their abilities, and these perceptions influence children's academic performance. This process is evident across cultures and within groups. In a comparison of Chinese and Anglo parents of primary school children, the parents' perceptions of their children's memory abilities and their expectations for their children's language and mathematics performance were consistent predictors of the children's achievement (Phillipson & Phillipson, 2007). In studies of African American families, parents reported lower academic expectations for their boys than for their girls. The relationship of gender to children's own expectations was strongly influenced by their parents' expectations (Wood, Kaplan, & McLoyd, 2007; Wood, Kurtz-Costes, Rowley, & Okeke-Adeyanju, 2010). In a longitudinal study of children in Baltimore, parents who had the fewest economic resources also had notably lower expectations for their boys' school performance, and these low expectations were mirrored in the boys' lower reading comprehension scores, even in first grade (Entwisle, Alexander, & Olson, 2007).

Expanding on the relationship between gender role bias and the socialization of children's competencies and interests, Eccles (1993) proposed the following model (see FIGURE 8.3 ▶): Parents' gender role stereotypes and beliefs influence their perceptions of their own children's competences and interests. These perceptions influence the kinds of experiences parents provide for their children and the types of encouragement or criticisms they communicate. Over time, this combination of parental beliefs and behaviors impact a child's assessment of his or her abilities and the amount of time and effort the child is willing to invest in various activities.

A number of studies support the underlying dynamics of this model. Parents' beliefs and behaviors, often influenced by gender stereotypes and social norms, influence their expectations for their children's academic futures (Davis-Kean, 2005). Independent of actual gender differences in specific domains, including math, sports, or English, parents' stereotypes about which gender is more talented in a particular area influence their perceptions of their own child's competence in that area. Parents' perceptions of competence are directly related to their children's perception of competence (Tiedemann, 2000).

FIGURE 8.3 ▶ The Relationship of Parents' Gender-Role Beliefs and Behaviors to Children's Beliefs and Behaviors

illusion of incompetence. In studies of gifted children, 20 percent to 30 percent underestimated their abilities (Phillips, 1984, 1987). The same phenomenon has been observed in regular classrooms of third and fourth graders. A subset of children systematically under value their abilities, despite objective test scores that indicate that they are performing as well as their peers (Bouffard, Boisvert, & Vezeau, 2003).

These children expect lower levels of success, are less confident, attempt less challenging tasks, and say that their schoolwork is more demanding than peers of similarly high ability who have more positive self-evaluations. They begin to identify with their lower-performing classmates. As the concept of self-efficacy would suggest, over time, children who have an illusion of incompetence are less likely to persist in the face of difficult work, and show a decline in school performance (Chayer & Bouffard, 2010; Larouche, Galand, & Bouffard, 2008).

Parents play a central role in establishing these children's low assessments of themselves. Children who have an illusion of incompetence see their parents as less available and more conditional in their support (Côté & Bouffard, 2011). They think that their parents have a low opinion of their abilities and expect little of them. They see their fathers, in particular, as having rigorous standards that they are not expected to meet. The parent–child dynamics that underlie this negative assessment were observed in a study involving children with high academic ability who had varying levels of perceived academic competence. Children worked with their mothers and fathers on solvable and unsolvable tasks. The fathers of children who had low perceptions of their own academic competence were found to interact with their children in more critical or unsupportive ways than did the fathers of children who had high perceptions of their academic competence. The children who had illusions of incompetence were more emotionally upset and dependent when they approached the unsolvable tasks (Wagner & Phillips, 1992).

Children may infer messages of incompetence from parental control. In a comparison of children in grades 2 through 5, the older children interpreted parental helping, monitoring, and decision making as evidence that the parents thought they were incompetent. As children get older and their desire for autonomy, initiative, and industry increases, they may interpret parental monitoring as evidence of a lack of confidence in their ability to make good decisions or to function competently (Pomerantz & Eaton, 2000).

In contrast to illusions of incompetence, some people have **illusions of competence**. In four separate studies, researchers found that those participants who scored in the lowest 12 percent of test takers on measures of grammar, logic, and humor substantially overestimated their own abilities. The extreme lack of ability in an area is accompanied by the inability to distinguish accurate from inaccurate responses, thus leading to a misconception of competence. In contrast to illusions of incompetence, where children underestimate their abilities, illusions of competence occur when people have such deficiencies that they do not even realize the extent of their limitations (Kruger & Dunning, 1999).

The discussion of self-evaluation highlights children's sensitivity to their social environment. They become aware of existing roles and norms and of the sanctions for norm violation. Direct experiences with success and failure are important, but they are also embedded in the context of social expectations. In this age period, with the skills of metacognition and perspective taking, children come to understand that people may alter their behavior in order to project an image that will receive a favorable evaluation from others. Under certain circumstances they may wish to alter their own self-presentation in order to receive positive social evaluation from parents, teachers, or peers. This kind of motivated modification of self-presentation is sometimes referred to as *brownnosing* or *kissing up*. Even though this behavior can be a subject of critical taunts from peers, the motivated student may realize that this strategy is necessary in order to receive positive evaluations or high grades. For example, Perry notices that his English teacher is especially nice to a friend of his who reads poetry during their free time. Perry knows that his friend is not at all interested in poetry, but that the friend has received positive grades from the teacher who believes that the child is really interested in English literature. Taking a cue from this strategy, Perry brings a book of poetry to class and makes frequent eye contact with the teacher to convey interest. The teacher now smiles at him more often, shows new interest in his ideas, and gives his written work a more positive evaluation. Perry concludes that the image he is presenting of himself as one who likes English literature is influencing his teacher's evaluation of his work. Thus, the notion that self-evaluation is shaped by the reflected appraisal from others becomes more complicated as children become skilled in image management (Banerjee, 2002; Hergovich, Sirsch, & Felinger, 2002).

By the end of middle childhood, children have had enough school experience that they can detect favoritism, bias, and unfair treatment and can devise strategies to protect themselves from the impact of negative biases. They are able to judge their abilities by considering their mastery level and the amount of effort they have to exert in order to do well. They can evaluate their own learning based on an understanding of general standards for performance, their own sense of increased mastery, and the opinions of others. They are able to decide when someone else might be a better judge of their abilities than they are (Burton & Mitchell, 2003; Elder, 2010). The more children are embedded in strong, supportive social relationships, the more confidence they will have in their general worth and the more likely they will be to arrive at accurate assessments of their own abilities.

FURTHER REFLECTION: *Examine the role of parents, peers, and teachers as they influence a child's self-evaluation in middle childhood. Explain how positive feedback and encouragement from one of these sources can make up for criticism or rejection from another.*

Team Play

OBJECTIVE 5 Summarize new levels of complexity in play as children become involved in team sports, examine the benefits of participation in sports, and analyze the cognitive and emotional development that accompanies team play.

During middle childhood, many children participate in team sports, which are generally more complicated than the kinds of games described as group play in chapter 7. The rules are complex, and they may require a referee or an umpire if they are to be followed accurately. In these sports, children join together into teams that remain together for the duration of the game. Some children join teams that play together for an entire season, such as Little League. Many children play on more than one type of team, rotating across activities with the seasons.

According to the Pew Research Center national survey, 73 percent of parents say that their children participated in sports/athletic activities over the past year. For many families, a child's participation in team sports is a family affair. Among the parents whose children are under age 13, almost 4 in 10 have helped to coach one of their children's sports teams (Pew Research Center, 2015c). While team play may not be for every child, it appears to be a normative aspect of middle childhood and an aspect of life that is accompanied by a number of physical, cognitive, and social benefits.

Health and Fitness

A growing interest in physical activity and fitness in adulthood has shed new light on the importance of involvement in team sports in childhood and early adolescence. Regular participation in sports helps build bones and muscles, enhances endurance and balance, and lowers risks of high blood pressure and the risks of obesity in adulthood. For most team sports, a sequence of fitness exercises including aerobic exercise, strength and flexibility exercises, and large and small muscle coordination are part of the practice and preparation for play. In a study of adult men ages 32 to 60, voluntary participation in team sports in middle childhood was linked to continued physical activity in adulthood (Taylor, Blair, Cummings, Wun, & Malina, 1999).

Even though participation in team sports is associated with many physical, social, and cognitive benefits, there are increasing concerns about potential risks to participation, especially risks of injury as well as the possibility of encountering coaches who are poorly trained or ill-suited to their role. When children perceive that their coaches endorse aggressive play or cheating, the players are also likely to act aggressively during play. Parents who are overly intense about pressuring their child or coaches who use aggressive techniques can both become forces that encourage rough, unsportsmanlike conduct that may result in injury (Malete, Chow, & Feltz, 2013; Sánchez et al., 2014).

A growing national concern focuses on the risks of traumatic brain injuries associated with some team sports. This issue has received wide public attention in the professional sports world, especially football, hockey, and soccer. The study of the incidence of concussions and the long-term consequences for brain damage among professional athletes has led to greater efforts to monitor concussions in high school and college players. As a result, the focus has drifted down to concerns about head injuries among children at younger ages when brain development is undergoing rapid transformation. However, more systematic documentation of incidences of brain injury among these younger players is needed. For 80 to 90 percent of the players who experience a sports-related concussion, full recovery is experienced within about 2 weeks. However, for the other 10 to 20 percent, recovery is more prolonged and may be associated with an array of cognitive and affective difficulties.

Three policy issues are needed to address this problem: (1) Guidelines for returning to play after a possible head injury. Often players don't want to leave the game because they don't want to let down their team. Coaches and team members may encourage players to return to play or "play through the pain" despite a possible concussive injury. The risks of a repeated concussion appear to be especially serious for young players. (2) Guidelines for returning to school or regular activities in order to support full recovery. A plan for gradual return to school and to play is needed and considerations for this process need to be supported by family, friends, teachers, coaches, and team members. (3) Guidelines for injury prevention. This may involve changes in the rules of play for younger players, use of new equipment, and practice in techniques that protect the head. The CDC recommends that a player who sustains a concussion should be immediately removed from play and not permitted to return to play until he/she has been cleared by a knowledgeable health professional (Institute of Medicine & National Research Council, 2013; Wahowiak, 2015).

Parents are urged to be aware of the safety precautions needed for each type of sport and the kinds of warm-up exercises and equipment needed to help prevent injuries. Attending practices and games in a supportive role is an important aspect of preventing the team environment from becoming abusive (KidsHealth, 2014). Not all children are interested in team sports as a path toward activity and fitness. Other options for children in this age range include bicycling, horseback riding, tennis, swimming, karate, fencing, skateboarding, ice skating, hiking and climbing, and golf. Each of these activities offers opportunities to incorporate physical activity in a child's daily life. However, each also poses some risks of injury and requires appropriate preparation, training, monitoring, and safety considerations.

In addition to its contribution to fitness and physical activity, team participation provides opportunities to spend time with friends and to celebrate together (Mowling, Brock, & Hastie, 2006). In addition, participation in **team play** provides a context for learning the social and interpersonal skills and strategies that will apply to work and family life in the years ahead (Van der Vegt, Emans, & Van De Vliert, 2001). Participation on a team may create a climate for collectivist values such as cooperation, interdependence, and the subordination of the individual's goals to the team's success (Kernan & Greenfield, 2005). Team participation raises issues of moral judgment and moral behavior, especially regarding fair play, cheating, sportsmanship, and prosocial or antisocial behaviors (Lee, Whitehead, & Ntoumanis, 2007). The following five characteristics of the experience of team membership contribute to development during this stage: (1) interdependence, (2) the division of labor, (3) competition, (4) cooperation, and (5) in-group and out-group attitudes.

Interdependence

Team membership carries with it an awareness that one's acts may affect the success or failure of the entire group. Although team sports do provide opportunities for individual recognition, team success casts a halo over even the poorest players and team failure a shadow over even the best. Participation in team sports provides lessons in **interdependence**. Team members rely on one another, and ideally, it is to everyone's advantage to assist the weaker members in improving the quality of their play. As reflected in a favorite saying of coaches, players, and newspaper reporters, "There is no I in team." Over time, the team provides what is sometimes referred to as a **superordinate group identity**, such that the individual members are willing to suppress their distinct racial, religious, or cultural differences and work together for the success of the group (Jackson et al., 2002). The best coaches are noted for inspiring this sense of interdependence and mutual support among team members. They urge team members to work together to improve their skills. Often, when teams are closely matched, it is the unexpected success of the weaker players that contributes to a victory.

Division of Labor

Through participation with peers on teams, children discover that **division of labor** is an effective strategy for attaining a goal. Children learn that each position on a team has a unique function and that the team has the best chance of winning if each player performs his or her specific function rather than trying to do the work of all the other players. The concept of the team suggests the notion of a system of interrelated roles and functions in which each of the team members actually engages.

A team becomes an experiential model for approaching problem solving in other complex organizations. Once children learn that certain goals can best be attained when tasks are divided among a group of people, they begin to conceptualize the principles behind the organization of social communities. They recognize that some children are better suited to handling one aspect of the task and others to handling another. Some children enjoy the skill development associated with team play; others enjoy learning the rules and devising strategies; others especially value peer companionship; and still others have a strong inner motive to compete and win (Ntoumanis, Vazou, & Duda, 2007). The distribution of roles to fit the children's individual skills and preferences is a subtle element of the learning that is acquired through team play.

Competition

Team play teaches children about **competition**. In team sports, both sides cannot win; success for one side must result in failure for the other. When children were asked to talk about their views of participating in team sports, they identified three major themes: sport as competition, sport as fun, and sport as fair play. From the children's point of view, coaches and parents are especially likely to be the ones to emphasize the competitive theme through the use of disciplinary techniques, language, and their relative power and authority (Walters, Payne, Schluter, & Thomson, 2015).

If the team experience is a laboratory for learning lessons about the larger social community, this characteristic promotes a view of social situations in competitive terms. Some adults think of business, politics, popularity, and even interpersonal conflicts as win-lose situations, in which the primary goal is to beat one's opponents. The idea of a win-win strategy to resolve conflict is very foreign in this context.

Many young adults have fond memories associated with winning an important game or a big match. They hope to re-experience the energy that occurs as a result of winning as they approach their adult activities. The metaphor of playing on a winning team is deeply interwoven into the world of work, helping to give focus and drive to day-to-day work-related obligations and tasks.

In contrast to those who are energized by the challenges of competition, some children are especially sensitive to the pain of failure. Children may be ostracized or ridiculed if they contribute to a team loss (Mowling, Brock, & Hastie, 2006). The public embarrassment and private shame that accompany failure are powerful emotions. Some children will go to remarkable extremes to avoid failing. In team sports, each game ends with a winning and a losing side. Some children who have a low sense of self-esteem may experience anxiety about losing in a competitive situation (Brustad, 1988). Involvement in

After a hard-fought game, the winners experience the positive emotions and feelings of pride and self-confidence that accompany winning.

team sports is guaranteed to bring with it some experience of losing—experiences that drive some children away from sports and into other domains of competence. On the other hand, some children just use the experience of losing to work harder. A trip for ice cream or milk shakes after a team loss can help erase any bad feelings and leave the team ready to face the next challenge.

Cooperation

Cooperation is a fundamental feature of evolution. Selection favors families and groups whose members are cooperative. In the evolutionary past, warfare between competing groups was common. Those groups that were able to foster greater cooperation among members had a better chance of survival (Pennisi, 2009). It appears that the human brain has evolved so that the individual acts to defend the group against threat, even if such efforts result in exposure to danger to the self. Under conditions of intergroup competition, the brain produces oxytocin, a hormone that enhances empathy, generosity, cooperation, and trust. The adaptive value of cooperation is supported by this hormonal activity, which strengthens the individual's positive sentiments toward the group and willingness to promote the group's welfare (De Dreu et al., 2010).

Team members learn that if the team as a whole is to do its best, the team members must help one another. Rather than playing all the roles, a team member tries to help every other member play his role as well as possible. In team play, **cooperation** takes many forms: Members share resources, take time to help other team members improve their skills, plan strategies together, work together on the field, encourage each other, bring out the equipment, or clean up after the game. Physical educators have found that they can use a cooperative teaching approach to enhance skills and strategy. When children are placed into groups to talk about the rules and skills needed for the sport, both motor skills and strategy use improved (Darnis & Lafont, 2015).

In many sports, there is a dynamic tension between competition and cooperation. Team members may compete with each other for a more desirable position or for the status of being the top player. At the same time, the team members know that they have to support each other, especially when they play against another team.

In-Group and Out-Group Attitudes

Team membership provides a microsystem for observing the formation of in-group and out-group attitudes and behaviors. All human societies observe distinctions between in-group and out-group attitudes and behaviors (Haidt, 2007). The **in-group** members share common norms, goals, and values. They also share a common fate—in sports, for example, the team wins or loses as a team. Feelings of cohesiveness with and similarity to members of an in-group prompt behaviors that are supportive of that group's survival. Members of a group typically behave in ways that are more accepting of other in-group members. This is referred to as **in-group bias**. Individuals distribute resources so that members of their in-group receive more and members of the out-group receive less. People are more forgiving of the limitations or weaknesses of members of their in-group and are more willing to give in-group members the benefit of the doubt. The more salient group membership is and the higher the status of the group in comparison to other groups, the more likely it is for group members to endorse positive attitudes toward other members of their group (Mullen, Brown, & Smith, 2006). When in-group norms emphasize fairness and reject discrimination, members are more likely to treat members of the out-group with fairness. Thus, in-group norms can influence the degree to which out-group hostilities are encouraged and expressed or suppressed (Jetten, Spears, & Manstead, 1996).

The **out-group** is any group whose goals are either in opposition to or inconsistent with the goals of the in-group. Any group may be perceived as an out-group, even though it does not actually pose any physical threat to members of the in-group. Students at one university may perceive students at another university as an out-group (e.g., the longstanding football rivalry between Ohio State University and the University of Michigan). Students enrolled in one program or major may view students in a similar but competing major as an out-group (e.g., chemical engineers versus electrical engineers). In experimental studies, in-groups and out-groups have been formed based simply on wearing a blue or yellow badge, or based on those with blue eyes and those with brown eyes (Verkuyten & De Wolf, 2007). Children as young as

Table 8.3 In-Group and Out-Group Attitudes That Develop Through Team Play Experiences

In-Group Attitudes	Out-Group Attitudes
The child learns	The child learns
1. To value and contribute to team goals	1. To view the goals of the opponents as inconsistent with the goals of the in-group
2. To subordinate personal goals to team goals	2. To view the outcome of competition as a zero-sum game, in which only one team can win
3. To receive and use feedback and help from team members	3. To recognize that helping the other team to win is unethical
4. To value one's role as an element in a larger system and the interdependence of the team members	4. To accept the necessity for antagonism between members of opposing teams
5. To recognize that team members share a common fate	5. To devise strategies that will exploit the weaknesses of the opponent

age 5 are aware of the status of their group. If they believe that their group has positive qualities and is valued, they are more likely to want to remain in the group and see themselves as similar to other group members (Bigler, Brown, & Markell, 2001; Nesdale & Flesser, 2001).

Children learn to see the outcome of competition as a win-lose situation. For sports teams, the out-group's goal of winning is in direct competition with the in-group's similar goal. The other team is seen as the enemy, and there is no alternative to trying one's hardest to defeat it. Antagonism toward the out-group is valued in team sports, and any attempt to assist the other team in winning is seen as unethical. Generalizing to the level of inter-ethnic or intertribal conflict, children may learn that moral principles that apply to members of the in-group do not necessarily apply to members of the out-group (Triandis, 1990). Here we see the primitive origins of inter-group prejudices. What can coaches do to help children understand the nature of these in-group and out-group processes and to minimize intergroup hostilities and prejudices?

Children may belong to more than one team. Depending on the situation, children can view one another as members of their in-group in one sport and as members of an out-group in another sport. For example, Ryan and his friend Tom were on the school soccer team together, but they belonged to different summer baseball leagues. During the summer, they had to compete against each other, so it usually turned out that they spent more time together and were closer friends during the school year than they were during the summers. Categorizing a peer as a member of an in-group or an out-group will lead to different attitudes and behaviors toward that person.

As children get older, their tendency to show unquestioning favoritism for their in-group is tempered by social reality and their experiences of participating in multiple groups (Verkuyten & De Wolf, 2007). They can evaluate information that suggests that one team or nationality or ethnic group is better than another and use that information to temper their in-group favoritism or their out-group prejudices. At the same time, functional messages that highlight the benefits of being in one group over another can strengthen in-group attitudes. For example, in one community, Japanese American families were concerned that their third and fourth generation children were losing their ethnic identity. In an effort to address this concern, they formed a Japanese American basketball league. Through this sports league, a context was created that strengthened the cultural network of Japanese American children and their families while engaging in an activity that has a clearly American cultural connotation (Chin, 2016). Table 8.3 shows the in-group and out-group attitudes that may result from experiences in team play.

Team Play as a Context for Development

Participation in team sports provides socialization experiences that have both positive and negative consequences. For most children, belonging to a team, making friends, learning new skills, and enjoying the sense of success associated with a collaborative effort are positive experiences. For example, in a study of what young people value about their sports experiences, most children placed the greatest emphasis on enjoyment, positive time spent with peers, and personal achievement, and the least emphasis on winning (Lee, Whitehead, & Balchin, 2000; MacDonald, Côté, Eys, & Deakin, 2011). However, we all know of instances where rivalries escalate into peer hatreds, children from neighboring schools turn against each other, and coaches humiliate and degrade children in order to instill a commitment to the team and a determination to win. Perhaps the question is whether—particularly in team sports—the focal point of the activity is to enhance children's natural impulses for competence and skill elaboration, or whether the team activity becomes a way for adults to vent their own frustrated needs for domination and power. So much depends on the coaches and the kind of team environment they foster.

Team play has implications for both social and intellectual development. Children who play team sports see themselves as contributors to a larger effort and learn to anticipate the consequences of their behavior for the group. Team play creates a valuable context for the formation of interpersonal relationships. Inclusion in a positive team experience often results in a child's identification with the coach and other team members. These new emotional investments can expand the child's sense of well-being and social support (Blanchard, Perreault, &

Vallerand, 1998; Wylleman, 2000). In a comparison of seventh-grade children who were or were not involved in organized team sports, teachers rated the children who were involved in sports as more socially competent and less withdrawn. There were no differences between the groups in aggression. However, among the boys, those involved in sports also reported a broader range of delinquent behaviors (McHale et al., 2005). Participation in a team can help buffer experiences of peer victimization. Children who were victimized at age 7 were followed to the age of 10. Those victimized children who participated in team sports were less likely to be victimized at age 10, less likely to suffer experiences of depression, and less likely to exhibit externalizing problems. The team experiences apparently helped these children to form meaningful social bonds and to have a sense of belonging that contributed to their well-being (Perron et al., 2012).

Games that involve teams typically require children to learn many rules, make judgments about those rules, plan strategies, and assess the strengths and weaknesses of the other players. All of these characteristics of participation in team sports can stimulate cognitive growth. In one study, for example, children were divided into soccer experts and soccer novices (Schneider & Bjorklund, 1992). The experts had an impressive depth of knowledge about the game of soccer and, when given a memory task involving soccer-related items, were able to use their expertise to perform at a high level. Through participation in the teaching and learning environment of a collaborative sports experience, the more skilled players can help advance the knowledge of their less skilled teammates, and at the same time, consolidate their own understanding as they try to explain various rules, strategies, and techniques to others (Darnis & Lafont, 2015).

Interest in sports and competitive team play has been used as a motivational hook to promote other areas of school ability. For example, children diagnosed with attention deficit/hyperactivity disorder (ADHD) were recruited for a basketball camp. Many of these children had difficulties regulating their impulses and showed poor social skills. The camp focused on athletic competence and sportsmanship. The combined efforts resulted in improved communication skills, reduced aggressiveness, increased interest in basketball as an activity, and some improvement in sports ability (Hupp & Reitman, 1999). Well-designed sports programs can have a broad impact on intellectual and social development by combining increased competence in physical activity with related emphasis on the cognitive and social components of team play.

FURTHER REFLECTION: *Consider the positive and negative aspects of participation in team sports during middle childhood. How can these experiences contribute to optimal development? How might they undermine development? Think about which kinds of experiences might benefit which kinds of children. How might a coach's attitudes about fair play, competition, cooperation, and the developmental needs of children influence the team atmosphere and children's experiences? What kinds of training and expertise should a person have about the process of team play and the sport he or she is coaching?*

The Psychosocial Crisis: Industry Versus Inferiority

OBJECTIVE 6 Explain the psychosocial crisis of industry versus inferiority, the central process through which the crisis is resolved, education, the prime adaptive ego quality of competence, and the core pathology of inertia.

According to psychosocial theory, with the resolution of the psychosocial crisis of industry versus inferiority, a young person's fundamental attitude toward work is established (Erikson, 1963). As children develop skills and acquire standards of self-evaluation, they make an initial assessment of whether or not they will be able to make a contribution to the social community. They also make an inner commitment to strive for success. Some children are keenly motivated to compete against a standard of excellence and achieve success. Other children have low expectations about the possibility of success and are not motivated by achievement situations. The strength of a child's need to achieve success is well established by the end of this stage.

Supporting the psychosocial perspective, results of the American Psychological Association's *Stress in America* survey indicated that in middle childhood children experience a variety of worries linked to the themes of industry and inferiority (Munsey, 2010). Among children ages 8 to 12, 44 percent worried about doing well in school; 28 percent worried about whether their family would have enough money; and 22 percent worried about getting along with their friends. Their worries are associated with physical symptoms including headaches, sleep disturbances, and upset stomachs. The survey found that parents tended to underestimate the extent to which their children were worrying about family finances or doing well in school and were often unaware of the physical symptoms their children were experiencing. These findings illustrate the domains in which the conflict of industry versus inferiority is being played out for children in the United States. Most children are keenly attuned to themes of evaluation and competence, not only in their academic lives, but also in social relationships, their parents' work environments, and family financial well-being.

Industry

Industry is an eagerness to acquire skills and perform meaningful work. During middle childhood, many aspects of work are intrinsically motivating. The skills are new. They bring the child closer to the capacities of adults. Each new skill allows the child some degree of independence and may even bring new responsibilities that heighten their sense of worth. In addition, external sources of reward promote skill development. Parents and teachers may encourage children to get better grades by giving them material rewards, additional privileges, and praise. Peers also encourage the acquisition of some skills, although they may have some negative input with regard to others. Certain youth organizations, such as scouting and 4-H, make the acquisition of skills a specific route to success and higher status.

In many low and middle income countries, children work to support their families. Often this work takes place in the family context where children help with household tasks, watch younger siblings, or contribute to farm or family business tasks. Children may work alongside their same-sex parent, learning the skills associated with their gender roles and contributing to their family's effective functioning. Under the best conditions, this kind of work can contribute to a child's sense of industry as children see how their work contributes to supporting the family and to gaining competences that will be valuable to their own future families.

There are also some negative consequences of child labor. When families in low and middle income countries rely too heavily on their children's labor for economic survival, this may prevent the children from attending school or from doing well in school. Some children are exposed to hazardous labor conditions that undermine their health and expose them to risks of injury. They may feel that they must work in order for their family to survive. Under these conditions, early experiences of work may undermine the sense of industry, creating feelings of anxiety, depression, and dread (Putnick & Bornstein, 2016).

Kowaz and Marcia (1991) described the construct of industry as comprising three dimensions:

1. The *cognitive* component of industry was defined as the acquisition of the basic skills and knowledge that are valued by the culture.
2. The *behavioral* component of industry was defined as the ability to apply the skills and knowledge effectively through characteristics such as concentration, perseverance, work habits, and goal directedness.
3. The *affective* component of industry was defined as the positive emotional orientation toward the acquisition and application of skills and knowledge, such as a general curiosity and desire to know, a pride in one's efforts, and an ability to handle the distresses of failure as well as the joys of success.

Children who resolve the psychosocial crisis of industry versus inferiority in the direction of industry are likely to anticipate their vocational pathway with optimism and confidence. The contemporary world of occupational decision making is complex, and career paths are uncertain. In middle childhood, children may not yet have a clear idea of their specific career path, but with a sense of industry they experience satisfaction associated with work and an appreciation that through work they can contribute in meaningful ways to their community (Marcia, 2014). It is easy to appreciate the value of a sense of industry as a psychosocial resource for young children as they face the variety of decisions that will be required in order to carve out a satisfying vocational future.

Sean Sprague/Alamy Stock photo

These young Honduran children experience a sense of industry as they help cultivate lettuce in their family field.

Inferiority

What experiences of middle childhood might generate a sense of **inferiority**? Feelings of worthlessness and inadequacy come from two sources: the self and the social environment. Children who cannot master certain skills experience some feelings of inferiority. Individual differences in aptitude, physical development, and prior experience result in experiences of inadequacy in some domain. No one can do everything well. Children discover that they cannot master every skill they attempt. Even a child who feels quite positive toward work and finds new challenges invigorating will experience some degree of inferiority in a specific skill that he or she cannot master. For example, students who are born just after the age cutoff date for a particular sports competition may find that they have a hard time competing with the slightly older children in their age group. Especially at younger ages, children who are matched with others who are 10 to 12 months older may experience disappointment when they cannot compete successfully (Musch & Grondin, 2001). For many children who have developmental delays or motor impairments, the challenge of experiencing mastery in school-based skills can be very frustrating. Disabilities that influence school success are discussed in the **Human Development and Diversity** box.

If success in one area could compensate for failure in another, we would be safe in minimizing the effect of individual areas of inadequacy on the overall resolution of the psychosocial conflict of industry versus inferiority. However, the social environment does not reinforce success in all areas equally. In post-industrial societies, skills in reading and math are much more highly rewarded than fishing or tinkering with broken automobile engines. Likewise, athletic skills associated with team sports are

HUMAN DEVELOPMENT AND DIVERSITY

Disabilities of Childhood and School Success

What happens when children have significant difficulty accomplishing the tasks associated with basic areas of school achievement? The centrality of success in school-based learning for a positive resolution of the psychosocial crisis of industry versus inferiority brings the problem of childhood disabilities to our attention. In 2012–2013, 6.4 million children (about 13 percent of public school children) received special education services in the United States under the Individuals with Disabilities Education Act (IDEA) (National Center for Education Statistics, 2015a). The most prevalent groups of disabilities were specific learning disabilities (35 percent), speech and/or language impairments (21 percent), health impairments (this includes a diverse group of health problems; 12 percent). Four groups of disabilities are described here, each one posing significant challenges for academic and social success during middle childhood and beyond.

Learning Disabilities

Learning disabilities are diagnosed when a child's skills and measured abilities in reading, mathematics, or written communication are well below the child's grade level and the level expected from the child's measured IQ. "Learning disabilities arise from neurological differences in brain structure and function and affect a person's ability to receive, store, process, retrieve or communicate information" (Cortiella & Horowitz, 2014, p. 3).

Learning disorders have been identified in approximately 5 percent of public school children in the United States. These children are differentiated from others who show low performance because of mental retardation, poor teaching, or cultural factors that interfere with school performance. Typically, learning disabilities are linked with deficits in the primary processing system, including speed and accuracy of information processing, attention, and memory. These deficits may be a result of genetic disorders, neurological damage during the prenatal period, or lead poisoning during childhood, but not all children with learning disorders have a history of these conditions. There have been many advances in early intervention, targeted instruction, and family support that contribute to school success for children with specific learning disabilities. Nonetheless, one third of students with a specific learning disability have been held back a grade at least once, and 19 percent drop out of school (Cortiella & Horowitz, 2014).

Communication Disorders

Some children experience difficulties in effective communication. Difficulties may include delays in acquiring new vocabulary; oversimplified grammatical expressions; limited variation in sentence types and structures; problems in sound production, such as lisping, omitting certain sounds in spoken speech, or stuttering; and problems in understanding certain types of words, expressions, and grammatical constructions. About 3 percent of children have some type of speech or language impairment that is distinct from mental retardation or a hearing impairment that influences speech (National Center for Education Statistics, 2015a). These difficulties interfere with academic performance especially because school learning involves the ongoing communication of information and ideas as well as the need to participate in social interactions with adults and peers. Children who have speech and language disabilities may have difficulty understanding social cues. They also likely to be the target of peer teasing and social ridicule, leading to a pattern of social withdrawal.

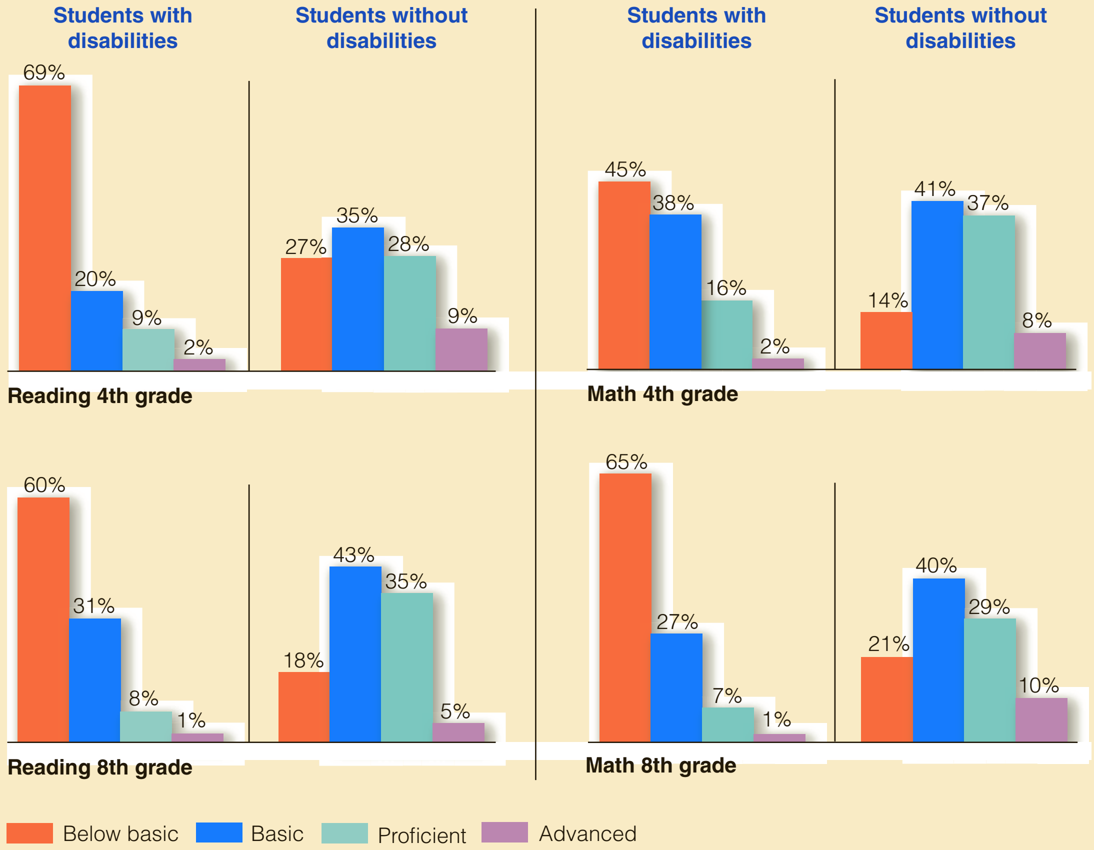
Health Problems

A range of health problems including a heart condition, asthma, sickle cell anemia, epilepsy, hemophilia, lead poisoning, and diabetes impact a child's vitality, strength, and/or alertness. Children with health problems may require the administration of medications during the school day. Depending on their health, some restrictions may be placed on their daily activities due to increased sensitivity to injury, limited endurance, or increased vulnerability to infection. These children may also encounter frequent absences if their health problems become more severe. Some health conditions change with age, requiring new approaches to treatment and management in the school environment. Managing one's health problems may make it challenging to succeed in school because of disruptions in the school routine, absences, anxiety about one's health and stamina, and feelings of being treated differently by teachers and peers. On the other hand, many children with health problems become more self-reliant as they take responsibility for managing their health needs.

Motor Skill Disabilities

Motor skills disorders, often referred to as developmental coordination disorders, may manifest themselves in a variety of ways, from mild to severe, including difficulty with large or small muscle coordination, speed of movement, muscle tone and strength, motor planning, and sensory integration (Nelson & Jaskiewicz, 2015). Children with these disorders may appear clumsy and delayed in the typical acquisition of early motor skills such as walking, running, tying their shoes, or using scissors or a knife. In later school years, they have trouble writing with a pencil or pen, are slow to develop skills in putting together puzzles or models, and their athletic skills, such as throwing and catching a ball, are delayed. These children are distinguished from others who have some broader medical diagnosis such as cerebral palsy. Their lack of motor coordination interferes with academic achievement to the extent that these children struggle with any kind of written assignment and have difficulty completing projects that require manual dexterity. They lack the satisfaction of excelling in physical activities because even simple motor skills such as running or playing catch are sources of frustration.

Learning disabilities, speech and language disabilities, health problems,



Note: Basic, proficient, and advanced reflect performance levels of knowledge and skills at each grade level.

FIGURE 8.4 ▶ Children with and without Disabilities Performance on National Assessment of Educational Progress, 2013

and motor coordination disorders are among the variety of mental, emotional, and physical disabilities that children may face as they struggle to resolve the crisis of industry versus inferiority. Depending on their severity, each of these conditions requires an individualized plan in order to help succeed in the daily tasks of schooling. Children who experience these disorders may find it difficult to carry out projects or to complete assignments that others view as simple. They may also become targets of peer teasing, bullying, or rejection. As a result, they may define themselves as incompetent, inferior, or unable to learn. FIGURE 8.4 ▶ summarizes how students with and without disabilities performed on the National Assessment of Educational Progress in fourth and eighth grade assessments of reading and mathematics (Cortiella & Horowitz, 2015). The figure illustrates the substantial performance gaps between children with and without disabilities at both the fourth and eighth grade levels.

With appropriate diagnosis and effective intervention, children can learn strategies to manage or compensate for their disabilities. Success in coping with a disability may, in fact, strengthen a child's self-confidence and provide a basis for beliefs of self-efficacy. Many children use the experience of coping with a disability as evidence that they can face and overcome other difficult challenges in their lives.

Critical Thinking Questions

1. Compare and contrast the kinds of problems children with each type of disability described in this box might experience in school.
2. Describe some implications of each of these disabilities for peer relationships and friendship formation.
3. Propose the steps that a family might take to support a child with each of these disabilities. What role might family members play with regard to school? Peers? The child's own self-evaluation?
4. Investigate the laws that address the responsibility of schools for meeting the needs of children with various types of disabilities. What might be some better approaches for supporting children with various special needs?
5. Propose some coping strategies that children might use to sustain their positive self-regard and to pursue high levels of school achievement.

more highly valued than skills for building a camp fire or planting a garden. It is difficult for a child who does not excel in culturally valued skills to compensate through the mastery of others.

The social environment also generates feelings of inferiority through the process of *social comparison*. Particularly in the school setting, but even in the home, children are confronted by statements suggesting that they are not as good as some peer, sibling, or cultural subgroup. Performance suffers when children face negative expectations. Children may be grouped, tracked, graded, or publicly criticized on the basis of how their performance compares with someone else's. For example, from a young age, children have internalized the expectations that boys are less academically able than girls. They hear this idea from parents and teachers, and come to believe it about themselves. As a result, negative stereotypes undermine many boys' beliefs in their ability and detract from their school engagement (Hartley & Sutton, 2013).

The intrinsic pleasure of engaging in a task for the challenge it presents conflicts with messages that stimulate feelings of self-consciousness, competitiveness, and doubt: "I like playing ball, but I'm not as good as Ted, so I don't think I'll play." As children become increasingly sensitive to messages of peer acceptance and rejection, they may refuse to try a new activity because they fear the possibility of being bettered or embarrassed by their peers.

The social environment may stimulate feelings of inferiority through the negative value it places on any kind of mistake or failure. Two types of failure messages may contribute to feelings of inferiority. One type consists of criticisms of the child's motivation or effort. Such criticisms imply that, if the child had really tried, he could have avoided failure. The other type refers to a lack of ability. Here, the implication is that the child does not have the basic aptitude to succeed. This type of failure message is associated with a pattern of attitudes about the self that has been described as learned helplessness.

"A person who has never made a mistake has never tried anything new." (Albert Einstein)

Learned helplessness is a belief that success or failure have little to do with one's effort and are largely outside one's control (Nelson, 1987; Seligman, 1975/1992). In a study of fourth, fifth, and sixth graders, children were asked to verbalize their thoughts as they worked on various tasks. The children's verbalizations following failure showed a clear difference between the mastery-oriented children and the helpless ones. The mastery-oriented children were able to keep a positive attitude, increase their problem-solving efforts, and use their past mistakes to correct their approach. The helpless children began to blame themselves ("I never did have a good memory"). They emphasized the negative aspects of the task or criticized their own abilities and tried to find ways to escape from the situation (Diener & Dweck, 1980).

Helpless children tend to discount their successes and, in response to even a few remarks about their lack of ability, generate a self-definition that leads them to take a pessimistic view of their future success. When faced with a difficult or challenging situation, children described as helpless experience a negative mood while working on the task, give up quickly, blame their failures on a lack of ability, and expect to fail in the future (Cain & Dweck, 1995). Messages about failure usually suggest that there is an external standard of perfection—an ideal that the child did not meet. A few failures may generate such strong negative feelings that the child will avoid engaging in new tasks in order to avoid future failure. Longitudinal research suggests that children who are identified as helpless in their approach to tasks in kindergarten continue to show evidence of these same behaviors, expectations, and emotions as first graders and as fifth graders (Ziegert, Kistner, Castro, & Robertson, 2001).

When children resolve the psychosocial crisis in the direction of inferiority, they do not think of themselves as having the potential to contribute to the welfare of the larger community. This is a serious consequence. It makes the gradual incorporation of the individual into a meaningful social group difficult to achieve. The irony of the psychosocial crisis at this stage is that the social community, which depends on the individual's motives for mastery for its survival, is itself such a powerful force in negating those motives by communicating messages of inferiority.

FURTHER REFLECTION: *Think back on your middle childhood years, between the ages of 6 and 12. Describe some experiences that made you feel competent and self-assured. Describe some experiences that led to feelings of inferiority or self-doubt. What steps can an adult, whether teacher, parent, coach, or mentor, take to help reduce feelings of inferiority and foster a sense of industry?*

Speculate about how the resolution of the psychosocial crisis of industry versus inferiority might influence a person's attitude and orientation to work in adulthood.

The Central Process: Education

Education is a culture's process for transmitting valued knowledge and skills from one generation to the next. Every culture must devise ways of passing on the wisdom and skills of past generations to its young. This is the meaning of **education** in its broadest sense. It is also the process through which standards are established for exemplary, acceptable, or unacceptable performance. Education is the central process through which children experience the sense of mastery and accomplishment associated with industry and the critical feedback or negative evaluations that are associated with inferiority.

Education is different from schooling. The term *education* can have different meanings across cultural groups. For example, in Spanish the word *educación* refers to the internalization of proper, respectful social behavior. The goal of *educación* is character development. For children growing up in indigenous communities of South and Central America, the cultural tradition for education emphasizes learning by keenly observing the activities of the adults around them and then participating as they feel ready (López, Correa-Chávez, Rogoff, & Gutiérrez, 2010). In the United States, the term *education* focuses on an individual's acquisition of knowledge and skill development, typically gained within the context of school or a formal program of instruction (Greenfield, Keller, Fuligni, & Maynard, 2003). The literature on education places an emphasis on test scores and grades as well as grade retention and graduation rates as indicators of academic achievement. However, these outcome measures do not capture the dynamic process of education that takes place as children participate in the social, cognitive, and emotional work of learning.

The practice of separating formal educational experiences from the direct, intimate, hands-on activities of home and community is only about 200 years old. Before the industrial revolution, most children were educated by assisting their parents in the tasks of home life, farming, trading with neighbors, and participating in religious life (Coleman, 1987). In the case of the nobility, children often had tutors who supervised their education at home. Today, however, schools bear the primary responsibility for education.

Teaching, which began as an extension of the parental role, has become a distinct profession. In our culture, formal learning takes place in a special building during certain hours of the day. To be sure, the success of that experience in promoting a child's skills and a sense of the self as a learner depends heavily on the ongoing involvement and commitment of family members (Hill & Taylor, 2004). However, schools play a key role in providing opportunities for skill development and mastery, contexts for assessment, social comparison, and self-evaluation, and socialization for the behavioral characteristics—including focus, persistence, and organization—that contribute to the formation of a personal sense of industry.

During the elementary school years, the goal of education is to help children develop the basic tools of learning. Central to this process is an introduction to the language of concepts, theories, and relationships that allow children to organize their experiences. Schools strive to develop verbal and analytic problem solving. Instruction focuses on rules, descriptions, and abstract concepts. Children are exposed to a range of disciplines and methods of inquiry for dealing with complex problems. Throughout the educational process, children are presented with problems of increasing difficulty. They are given many opportunities to practice their newly developing skills, receiving continuous feedback about their level of competence.

In addition to the acquisition of skills and knowledge, schools emphasize an approach to behavior that can be described as a combination of *citizenship, social competence*, and *study habits* Schools impart a code of conduct that is intended to facilitate the teacher's ability to guide students' attention, help children organize and focus on the tasks at hand, and foster a respectful, cooperative attitude toward adults and peers. Within this framework, all of these qualities become part of the sense of industry for those children who adapt well to the culture of schooling.

Teachers' expectations about their students influence the kind of educational climate that they create (Jussim, Robustellli, & Cain, 2009). When teachers expect students to do well and to be highly motivated to learn, they tend to direct more encouraging emotional signals to those students. They smile more, offer them more encouragement, and interact in a warmer, more supportive tone. Their feedback to these students tends to focus more on their academic performance, and not as much on their behavior or their attitude. Teachers spend more time with the students whom they perceive as having academic potential, giving them more of their attention and challenging them with more interesting assignments. Finally, when teachers have high expectations for students, they give the students more opportunities to participate; they call on these students more often, give them more time to answer questions, and encourage them to be involved. All of these strategies convey to the students that the educational process is both welcoming and interesting.

Some children do not do well in this culture of schooling; they do not bring the expected social behaviors or study habits; they do not demonstrate the desired qualities of cooperation, self-regulation, or rule compliance. As a result, they receive negative evaluations, which contribute to feelings of inferiority, leading to a gradual disengagement from the educational experiences of school. Low school-engagement behaviors in the early elementary grades are as strong predictors of dropping out of school as are grades and test scores (Alexander, Entwisle, & Kabbani, 2001; Entwisle, Alexander, & Olson, 2007). In contrast, teachers who create classroom environments that are warm and supportive, well managed, and where students are encouraged to tackle challenging projects can help students overcome their reluctance and remain engaged in the learning process (Kim & Cappella, 2016).

In the United States, socioeconomic status (SES) and student achievement are strongly related. Differences in academic performance between children from low-resource and high-resource families are noted beginning as early as preschool. These differences have been attributed to variations in parents' investment in their children's schooling; disparities in the resources available to schools; differences in children's cognitive, social, and emotional maturity that support school engagement; and discrepancies in opportunities to learn, both in school, after school, and in the summer (Schmidt Burroughs, Zoido, & Houang, 2015).

Schools, as institutions of the larger communities they serve, may not have the same expectations for success for all the students who attend. And children and their families do not all bring the same degree of trust in the educational process to their schooling. In some cases, parents find that they have no access to or voice in decisions affecting their children. They and their children experience barriers to achieving success in the skills that schooling values. For example, in a study of Latino immigrant families, parents experienced language barriers, an inability of teachers to explain their children's school difficulties, and constraints in making contact with teachers. Even though parents expressed a desire to support their children's school success, they felt helpless and dismissed as they tried to make contact with the school (Ramirez, 2003). The sense of inferiority can be provoked for children when they perceive that the school devalues or disrespects their parents.

In some cases, inferiority is inflicted on children through abusive treatment by school adults. In the United States, in a single school year over 200,000 children were victims of corporal punishment in their schools, a practice that is legal in 20 states. African American children and children with disabilities were overrepresented in the percentages of groups who were punished by paddling and other physical means (Murphy, Vagins, & Parker, 2010).

Failure in school and the public ridicule that it brings play a central role in the establishment of a negative self-image, which can readily be linked to the sense of inferiority. Sometimes, children defend themselves against the threat of failure messages by blaming others for their failures or by bragging that they can succeed in other ways. Much as it may appear that these children do not care about school or the school's goals, the school remains a symbol of cultural authority. Children in these groups may conclude that the only way to retain a basic sense of self-confidence is to withdraw from school and try to establish their competence among their peers by accelerating their transition to adulthood through more risky paths (Alexander, Entwisle, & Kabbani, 2001; Clark, 1991; Gregory, 1995; Ogbu, 1987).

FURTHER REFLECTION: *Describe how the environment of school changes from age 6 (grade 1) through age 12 (grade 6). How well do these changes in the school environment match the developmental changes that take place during these two stages of life?*

Imagine that you were asked to provide guidance to a local school board about improving their elementary schools. What ideas from this chapter might inform your recommendations?

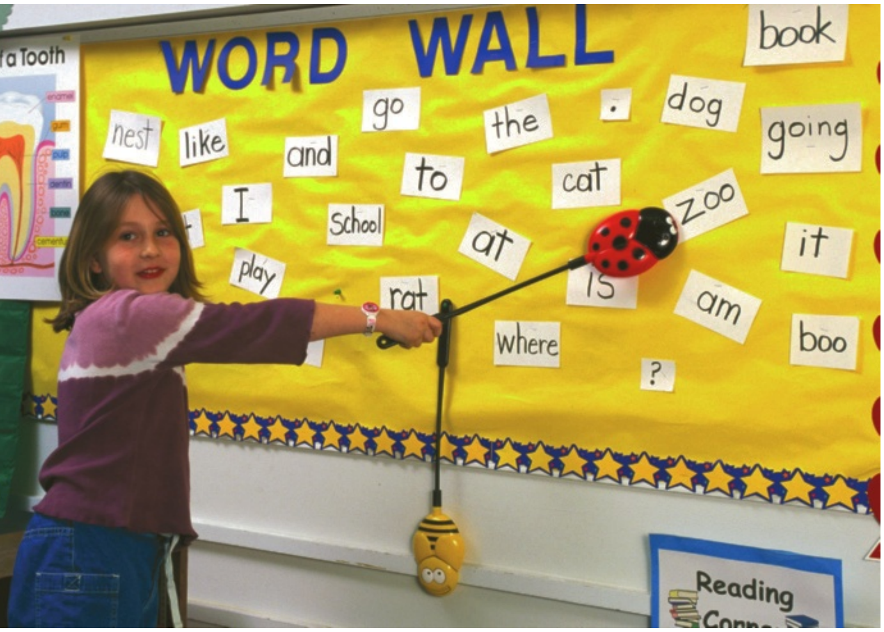
The Prime Adaptive Ego Quality and the Core Pathology

Competence

Erikson's (1982) notion of **competence** as the prime adaptive ego quality is a belief in the ability to make sense of and master the demands of a situation.

> Competence, in turn, is the free exercise of dexterity and intelligence in the completion of tasks, unimpaired by infantile inferiority. It is the basis for cooperative participation in technologies, and it relies, in turn, on the logic of tools and skills. (Erikson, 1978, p. 30)

Similar to the concept of self-efficacy, competence refers to confidence in one's ability to engage in new situations and do well. This idea is illustrated by a study that monitored children's perceptions of competence during school transitions from grade 5 to 6 and from grade 6 to 7. The children who had the highest levels of perceived competence also had the strongest positive feelings about how they were doing in school and showed the highest scores on a measure of intrinsic motivation. They wanted to be challenged by their schoolwork and they liked working independently and figuring things out for themselves. They expressed curiosity about the tasks, saying they would work hard because of their own interest rather than to please the teacher or to get good grades (Harter, Whitesell, & Kowalski, 1992). Children who have positive assessments of their cognitive competence anticipate future school successes; children who have positive assessments of their social competence anticipate improvements in their future peer relationships (Wang & Koh, 2015).



David Young-Wolff/PhotoEdit

Erika is an excellent student who enjoys teaching others. Here she is demonstrating her reading and spelling competence as she guides the class in a word-recognition activity.

Children who have internalized a sense of competence love to learn and work. They are excited about developing new skills and are optimistic about being able to achieve success. These children are the ones who sign up for new activities or start neighborhood clubs, want to be on two or three sports teams, look forward to field trips and school projects, and take pleasure in being asked to help with difficult tasks like planting trees along the highway, building a new playground, or raising money for earthquake victims.

Inertia

Inertia is the core pathology of middle childhood. In Erikson's words, "The antipathic counterpart of industry, the sense of competent mastery to be experienced in the school age, is that inertia that constantly threatens to paralyze an individual's productive life and is, of course, fatefully related to the inhibition of the preceding age, that of play" (1982, pp. 76–77).

Children who leave early school age with the core pathology of inhibition fail to participate and engage much during middle childhood. These are not the students who try and fail repeatedly, nor are they the ones whose sense of competence must be reconfirmed daily. Instead, they are students who tend to be passive and withdrawn, never engaging psychologically with the demands of their schools or their communities. Growing from this reticence to engage, the core pathology of inertia leaves a child listless and unable to summon the energy and will to participate in new activities or to prepare for a different, more positive future.

Children who leave middle childhood with a sense of inertia continue to be withdrawn and passive. They have trouble instigating actions or changing the course of events in their lives. As a result, they will not be likely to address challenges or problems by formulating plans of action, evaluating them, and then executing them. Children with a sense of inertia will not believe that they can master the challenges they face, and thus, they are likely to be swept along by the tide of events.

We all experience periods of inertia—times when we cannot muster the energy, enthusiasm, or confidence to take action. We may become besieged by doubts about our competence and worth—doubts that can produce work blocks, writer's block, waves of fatigue, boredom, procrastination, or aimlessness. Typically, one can survive a few days or even weeks on automatic pilot, doing the bare minimum to survive. Children may be able to get by for quite a while without exercising much energy or direction, especially if they are being sustained by parents and teachers. Eventually, however, life brings demands for change and expectations to meet new challenges that have never been faced before. Children who believe in their competence and their ability to learn can direct their willpower to overcoming obstacles; they will respond to these challenges with resilience (Yeager & Dweck, 2012). Children who are burdened with a pervasive sense of inertia may be unable to cope.

Applied Topic: Violence in the Lives of Children

OBJECTIVE 7 Evaluate the impact of exposure to violence on development during middle childhood.

The problem of violence in families, schools, and neighborhoods threatens to undermine the quality of the psychosocial development and educational attainment for many American children. Exposure to violence has potential damaging effects on cognitive, emotional, social, and physical development. Based on a national survey conducted by the U.S. Department of Justice and the CDC, an estimated 58 percent of children under age 17 had experienced one or more incidences of violence in the past year including physical assault, sexual victimization, maltreatment, property victimization, and witnessing violence. Almost half of the children had experienced more than one of these types of violence in the past year. Among children in the age group 14 to 17, almost 70 percent said that they have been a victim of some type of physical assault in their lifetime (Finkelhor, Turner, Shattuck Hamby, & Kracke, 2015). The topic of violence in the lives of children illustrates the interaction of the biological, psychological, and societal systems as they contribute to developmental trajectories.

Consequences of Exposure to Violence

Three consequences of exposure to violence are of especially grave concern: children are victims of violence; children become more violent; and exposure to violence disrupts cognitive functioning and mental health.

Children as Victims of Violence

As a result of the violence in their families and neighborhoods, large numbers of children and youth are victims of violent crimes. Among 14 to 17 year olds, almost a third said they had been injured as a result of an assault in their lifetime (Finkelhor et al., 2015). According to the CDC, 279 children ages 5 to 14 died due to homicide in 2014. Homicide was the third leading cause of death for adolescents and young adults ages 15 to 24 in the United States (CDC, 2016). Children who live in low-income neighborhoods are especially vulnerable to exposure to violence. According to a report issued by the National Center for Education Statistics and the Bureau of Justice Statistics, in 2009–2010, 1,183,700 violent crimes were committed in public schools (Robers, Zhang, & Truman, 2012). Findings from this report suggest that the younger students are more fearful than the older students about the chances of being harmed at school.

In a survey of fifth graders who live in a very poor urban district in the Northeast, 82 percent reported being victimized at school, including being hit by another student, kicked or pushed by a student, threatened with a knife or other weapon, verbally threatened, or robbed. Ninety-three percent of the children had observed one of these forms of violence being directed to other students at their school (Cedeno, Elias, Kelly, & Chu, 2010). Neighborhoods that are centers of illegal drug trade are also often the sites of violence, including stabbings, shootings, and gang raids. In these communities, the loss of a legitimate economic base, with few people in stable or high-status occupations, leads to takeovers by gangs and other organized criminal activities. Children may be lured into dangerous forms of drug-related transactions, which make them targets of violence on the streets as well as victims of abuse by drug-addicted family members and youth. Once involved in some aspect of drug trafficking, these children are more likely to be exposed to other forms of community violence (Li, Stanton, & Feigelman, 1999; Okundaye, 2004).

Anadolu Agency/Anadolu Agency/Getty Images

Syrian children have been exposed to years of violence. Two children leave the territory of their home as battle rages around them. Imagine the long-term impact of ongoing violence and family disruptions on this generation of children.

Exposure to Violence and Aggressive Behaviors

Many studies report a significant relationship between victimization or witnessing violence and carrying out violent actions on others. Initial reactions to community violence may lead younger children to feel wary, worrying that they or their friends or family members might become victims. However, over repeated exposure to community violence, children may come to accept violence as predictable and normative in their neighborhood. As a result, they may begin to see violence as an adaptive approach to conflict (Kennedy & Ceballo, 2016). The accumulation of exposure to violence across several settings, including community, school, and home, coupled with low parental monitoring and the likelihood of being a victim of violence, creates a context in which children engage in risky and more serious violent behaviors as an adaptive response to the chaos of their home and community (Boxer et al., 2013; Garbarino, 2001; Saltzinger, Rosario, Feldman, & Ng-Mak, 2008).

Exposure to Violence Disrupts Cognitive and Emotional Development

Intense, frequent, or prolonged exposure to one or more forms of violence can be considered toxic stressors. Exposure to these stressors has been associated with serious detrimental consequences for physical health, cognitive functioning, and mental health (Moffitt & the Klaus-Grawe 2012 Think Tank, 2013; Shern, Blanch, & Steverman, 2016). Children who have been severely abused or exposed to intense violence may be suffering from symptoms similar to post-traumatic stress disorder. **Post-traumatic stress disorder** can result from direct experience of a grave threat to personal safety or injury, witnessing the injury or death of another person, or learning about the violent death or injury of a family member or someone close. The response usually includes "intense fear, helplessness, or horror." The person typically has recurrent vivid recollections or dreams of the event with accompanying strong emotional reactions. Children may have recurring nightmares, repeat the same play sequences that re-enact some part of the traumatic event, withdraw interest from activities they used to enjoy, and show physical symptoms that they did not have before the event, such as stomach aches or headaches. School-age children may believe that there were warning signs that would have allowed them to avoid the trauma if they had been alert enough to recognize them. As a result, these children maintain a type of **hypervigilance** or increased arousal, directing their attention to threat-related stimuli (Dalgleish, Moradi, Taghavi, NeshatDoost, & Yule, 2001; Hamblen & Barnett, 2016; Osofsky, 1995). These symptoms often interfere with sleep, schoolwork, concentration, and normal social life.

Symptoms of post-traumatic stress disorder can be long lasting and, in some cases, can emerge long after the event has passed. For example, one study focused on 69 children who had lived within 100 miles of Oklahoma City in 1995 when the federal building was bombed. These children, studied in 1997, did not see the explosion, they did not live near the explosion, and no one they knew personally was injured or killed in the explosion. Yet 2 years after the event, many of these children showed evidence of post-traumatic stress disorder symptoms and related difficulties in functioning. Their symptoms were attributed to experiences of the event through the media and indirect loss through friends or family members who knew someone who was killed (Pfefferbaum et al., 2000). It is reasonable to expect that even when they are not the targets or victims of violence, the children who are present at school shootings, bombings, or beatings will have enduring symptoms associated with exposure to these violent events.

The Neurobiology of Exposure to Violence. Children preserve sensory and motor memories of the conditions associated with their trauma, which are then released under contemporary conditions of fear. In boys, these symptoms commonly reflect **hyperarousal**, including startle response, increases in heart rate, sleep disturbance, anxiety, and motor hyperactivity. In girls, the symptoms are more likely to be dissociation, gastrointestinal symptoms, and pain. Under threatening conditions, children who have been traumatized in the past automatically return to these disruptive states, making it difficult to access higher order problem-solving and reasoning skills.

Exposure to severe trauma may produce long-lasting changes in the way a child's brain regulates emotional reactions, the ability to concentrate, and the ability to inhibit impulses (Moffitt et al., 2013; Peckins, Dockray, Eckenrode, Heaton, & Susman, 2012). Simple regulatory and impulsive functions are governed by the more primitive, reactive areas of the brain, including the brain stem and the midbrain. More complex functions of language and abstract reasoning develop later and are located largely in the subcortical and cortical areas. The ability to modify and regulate impulses involves the coordination of two neurological pathways, one which provides intense signals about threats or dangers emerging from the brain stem, and the other which provides ideas about alternative coping strategies emerging from the cortex. An overreactive brain stem that produces intense and frequent impulses may result from any one or a combination of factors, including fetal exposure to alcohol and drugs, environmental exposure to lead, hormonal abnormalities, head injuries, or exposure to child abuse. Children reared in a socialization environment of chaos, violence, parental aggression, and harsh and abusive discipline lack the opportunity to develop empathy, self-control, and higher order problem-solving skills that might allow them to modulate their strong impulses.

Preventing Violence

Preventing violence in society and reducing exposure to violence among children have become significant public health issues (Shern, Blanch, & Steverman, 2016). Rather than focusing solely on the criminal justice definitions and strategies for deterrence, a public health perspective emphasizes the need to understand the contexts of violence from which strategies for prevention can be devised and evaluated. An ecological systems perspective leads us to consider the layers of influence that produce violence in the lives of children including the larger international conflicts that result in warfare and terrorism, the violent crimes that occur in neighborhoods, the aggressive acts that children experience in their homes and schools, and the representation and glorification of violence in music, movies, and video games. Some children are less able to regulate their impulsive reactions than others. Some children are more likely to perceive actions as threatening, and as a result, are more likely to strike out against others. We must try to determine what kinds of socialization environments can help children control their aggressiveness. Furthermore, we must discover strategies to reduce violence in families, neighborhoods, schools, and the media. Several directions for prevention have been identified and require coordination (Farrington, 2013; Low & Mulford, 2013; Matjasko et al., 2012):

1. Prevent prenatal and perinatal conditions that cause neurological damage and increase the biological vulnerability for violent behaviors.
2. Educate parents about ways to resolve their own conflicts so they do not continuously expose their young children to interpersonal violence in the home.
3. Develop techniques that parents and teachers can incorporate to help children acquire self-control, empathy, and perspective taking.
4. Strengthen the teaching and learning environment of schools in order to encourage greater school engagement and cooperative learning.
5. Develop effective techniques for teaching children how to reframe cognitions and beliefs that lead them to interpret the behaviors of others as threatening and develop alternative, nonaggressive strategies to handle and respond to insults, threats, and frustration.
6. Decrease children's access to guns and other weapons.
7. Increase the sense of social control and cohesion in neighborhoods so that mutual trust is higher, people help one another more, and people are more willing to take steps to intervene when children are acting destructively.
8. Improve coordination and cooperation among community agencies to strengthen the reach and effectiveness of interventions.
9. Implement social policies to reduce unemployment; improve safe, affordable housing; and encourage business development.

A variety of programs are being implemented to help reduce violence. Some focus on providing information about the problem and strategies for avoiding violence; some use role-playing, modeling, feedback, and reinforcement to alter students' behaviors; and some go beyond the classroom and the school environment by involving parents and community leaders to create a safe community where people are encouraged to practice positive behavioral interactions. In a review of 53 studies that evaluated universal school-based programs, researchers found that these programs were generally effective in decreasing violence (Hahn et al. & Task Force on Community Preventive Services, 2007). School-based programs that are delivered to all the children in the school rather than targeted to children who are at special risk for exposure to violence not only succeed in reducing violence but are also often associated with reduced truancy, improved school achievement, and improved social skills among students. One significant challenge facing these initiatives is discovering how to expand their reach from one school, community, or county to a wider population while preserving the specific features of the intervention (Hawkins et al., 2015). To learn more about strategies that are designed to prevent violence in schools, families, and communities, visit the website Blueprints for Healthy Youth Development (www.blueprintsprograms.com) to read about model programs that meet rigorous standards to evaluate effectiveness.

FURTHER REFLECTION: *Investigate the neurobiological effects of exposure to violence for children. What might be the immediate and more long-term impacts of these experiences? Evaluate the concept of toxic stress. Given what you know about the developmental tasks and psychosocial crisis of middle childhood, how might exposure to toxic stress compromise development during the middle childhood years?*

CHAPTER SUMMARY

During middle childhood, cognitive and social skills develop that are crucial to later life stages. Remarkable synergies occur across the cognitive domains, bringing new levels of skill development, expanded access to information, and complex strategies for approaching and solving problems. Children apply their cognitive abilities not only in academic, school-related domains, but also in an increased capacity for social competence, self-evaluation, and peer group participation. As a result of the combination of cognitive and social skill development, children are able to make significant contributions to the social groups to which they belong. They are also likely to seek approval and acceptance from these groups.

OBJECTIVE 1 Examine the role of friendship in helping children learn to take the point of view of others, be sensitive to the norms and pressures of the peer group, and experience closeness in relationships. Summarize the negative consequences that result from social rejection and loneliness.

The family environment provides the early context in which social competence emerges. The child's ability to establish and preserve friendships in middle childhood is built upon earlier capacities including temperament, attachment, sibling interactions, and the family's orientation toward peer relationships. Three important lessons are gained through participation in friendship: increasing appreciation for various points of view, awareness of peer norms and expectations, and a growing capacity for intimacy. As the role of friendship increases, problems tied to loneliness, rejection, and peer victimization become increasingly distressing.

OBJECTIVE 2 Describe the development of concrete operational thought, including conservation, classification skills, mathematical reasoning, and the child's ability to understand and monitor his or her own knowledge and understanding.

In early and middle childhood, new cognitive capacities focus on mental operations that provide a logical system of relationships among objects. Three achievements of this stage of reasoning include the scheme for conservation, classification, and combinatorial skills. A hallmark of this period is an increase in logical, focused problem solving. Children are able to consider competing explanations, look at a problem from another person's point of view as well as their own, and use information to plan a strategy to reach a goal.

OBJECTIVE 3 Analyze the nature of skill learning and examine societal factors that provide the contexts in which skill learning occurs.

An understanding of skill development combines an appreciation of the child's intellectual maturity with a sense of the significant motives that may influence willingness to learn. Skilled actions require adaptation to a cultural context. Skill development involves the integration of multiple domains that may mature at different rates. Skilled behavior involves the coordination of simple and complex elements as well as overarching strategies to achieve specific goals. Reading is discussed as an example of a skill that begins as a focus of its own (learning to read) and then becomes integrated into the achievement of many other skills (reading to learn). Health-related skills are discussed as an example of a domain that contributes to personal well-being.

OBJECTIVE 4 Outline the factors that contribute to self-evaluation, including feelings of pride, self-efficacy, and ways that social expectations of parents, teachers, and peers contribute to a child's self-evaluation.

The combination of advanced reasoning through concrete operational thought and engagement in a more complex peer environment contribute to new approaches to self-evaluation. The themes of pride, self-efficacy, and sensitivity to the social expectations of others are all relevant to understanding how children evaluate their competence or incompetence, and their willingness to strive toward new levels of achievement. The idea of domains of competence suggests that children are forming a more differentiated evaluation of their abilities. Children may form a self-evaluation as they reflect on their past performance, their comparison to peers, and messages from teachers and parents.

OBJECTIVE 5 Summarize new levels of complexity in play as children become involved in team sports, examine the benefits of participation in sports, and analyze the cognitive and emotional development that accompanies team play.

Participation in team sports can provide important health benefits that set the stage for continued activity in adulthood. They can also introduce risks of injury, with special attention to head injuries. Coaches and parents play a central role in creating a safe and cooperative environment for the unfolding of team experiences. Team sports offer a new and more complex form of play that combines the need for advanced levels of skill, cognitive capacities to understand rules and strategies for success, and interpersonal skills related to interdependence, cooperation, division of labor, and competition. Experiences regarding the formation of in-group and out-group attitudes are part of team sports. Team sports provide a microcosm of intergroup and intragroup relations that will be repeated in various contexts through adult life.

OBJECTIVE 6 Explain the psychosocial crisis of industry versus inferiority, the central process through which the crisis is resolved, education, the prime adaptive ego quality of competence, and the core pathology of inertia.

Industry focuses primarily on building competence. The family, peer group, and school all play their part in the support of feelings of mastery or failure, industry or inferiority. Education is the central process through which children discover the core understanding of the skills that are valued in a society and the paths toward their achievement. In our society, school is the environment in which continuous attention is given to the child's success or failure in basic skill areas. The child's emerging sense of industry is closely interwoven with the quality of the school environment and the extent to which the child encounters experiences that foster enthusiasm for new learning and provide objective feedback about levels of mastery. A positive resolution of the psychosocial crisis of industry versus inferiority is accompanied by a prime adaptive ego quality of competence. A negative resolution of the crisis is accompanied by the core pathology of inertia, leading to a passive disengagement from the opportunities and challenges of school and community life.

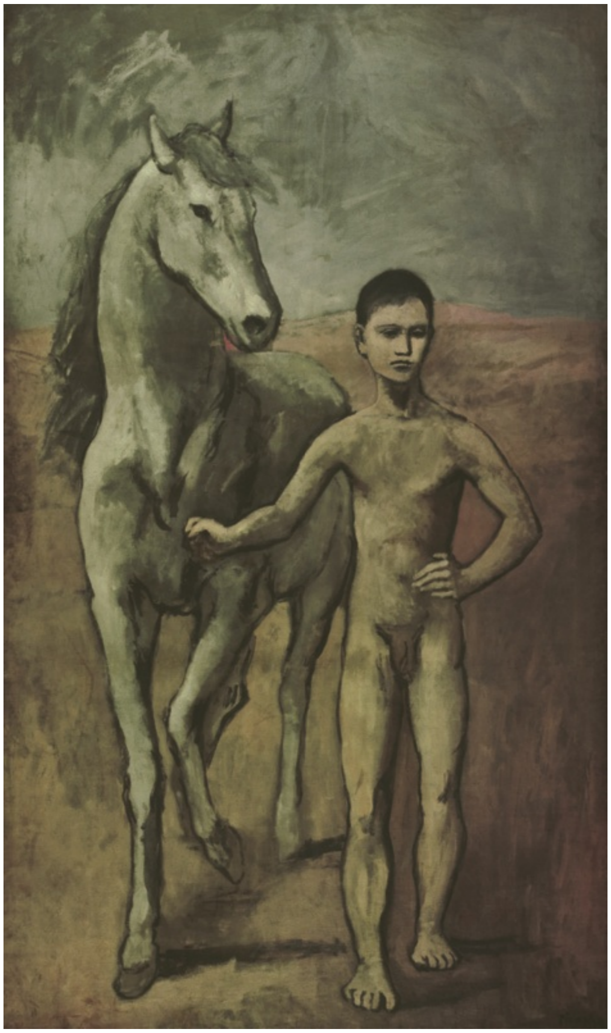
OBJECTIVE 7 Evaluate the impact of exposure to violence on development during middle childhood.

The Applied Topic illustrates the biological, psychological, and societal contexts of violence. Children can be exposed to prenatal and perinatal risks that disrupt their neurological development. They may be embedded in a family system in which abusive or disorganized parenting reduces their ability to cope with threats or stress. Violence in the neighborhood, media, and school strengthens impulsive, reactive responses and makes it increasingly difficult for children to draw on their higher order reasoning skills to reinterpret or interrupt their sense of anger and threat. Access to weapons, especially guns, leads to new heights of destructive expression for these children. Preventive interventions can be effective. However, they require a multilevel approach and coordination of family, school, and community agencies to support a positive, reassuring environment in which children can approach skill development and social relationships with confidence.

The achievements of middle childhood contribute in key ways to coping and adaptation in adulthood. Issues of industry, mastery, achievement, social expectations, social skills, cooperativeness, and interpersonal sensitivity are all salient themes during this stage. A person's orientation toward friendship and work—two essential aspects of adult life—begin to take shape.

CASEBOOK

For additional case material related to this chapter, see the case entitled "Ayesha and the Dinosaurs," in *Life Span Development: A Case Book*, by Barbara and Philip Newman, Laura Landry-Meyer, and Brenda J. Lohman, pp. 100–104. The case suggests how new cognitive skills, skill learning, and a sense of competence come together to promote new levels of leadership and problem solving in middle childhood. The case also illustrates some of the challenges that children face in the transition to kindergarten and how home, preschool, and kindergarten systems can work together to foster a child's continuing school success.



SuperStock

In early adolescence, physical changes of puberty are accompanied by alterations in the self-concept. The biological, psychological, and societal systems conspire to accelerate the transition along the path from childhood toward adulthood.

LEARNING OBJECTIVES

1. Describe the patterns of physical maturation during puberty for female and male adolescents, and analyze the impact of early and late maturing on self-concept and social relationships.
2. Summarize the development of romantic and sexual relationships, and evaluate the factors that influence the transition to first intercourse, the formation of a sexual orientation, and pregnancy and parenthood in early adolescence.
3. Identify the basic features of formal operational thought, and explain the factors that promote the development of advanced reasoning at this period of life.
4. Examine patterns of emotional development in early adolescence, characterize the neurological processes associated with emotional expression, and describe the nature of three problem areas: eating disorders, depression, and delinquency.
5. Analyze the nature of peer relations in early adolescence, especially the formation of cliques and crowds, and contrast the typical relationships with parents and peers during this stage.
6. Explain the psychosocial crisis of group identity versus alienation, the central process through which the crisis is resolved, peer pressure, the prime adaptive ego quality of fidelity to others, and the core pathology of isolation.
7. Apply your understanding of developmental issues of early adolescence to an analysis of factors that account for patterns of adolescent alcohol and drug use.

Applied Topic: Adolescent Alcohol and Drug Use
- Physical Effects of Alcohol
- Factors Associated with Alcohol Use

Chapter Summary

— CASE STUDY Evelyn Cabrera: Balancing Autonomy and Closeness in Early Adolescence —

Evelyn Cabrera is a seventeen-year-old second generation Mexican-American living in a working class neighborhood of a large urban area in the southwest with her parents, three brothers, and one sister.... She spends most of her time at school, her job, a local theme park, family events, and with her boyfriend.

Evelyn describes her relationship with her mother as very close:

> We're close, like really close; we communicate a lot. For example, when I have a problem, I tell her what's going on in my life, about my boyfriend, or about my friends, in school; yeah we're pretty close.

She doesn't communicate as often with her father because he works long hours, but she feels she can talk to him about anything as well—that is except for her relationship with her boyfriend. Evelyn and her boyfriend are serious, talking and thinking of marriage. He is older—in his twenties and has a steady job as an office manager for a health care company. Evelyn is Daddy's little girl, and he has a hard time thinking about letting her go....

Evelyn's father thinks she is too young for this level of seriousness in a relationship, and he tries to limit their contact by keeping her involved in family activities and responsibilities. Still, she spends a lot of time with her boyfriend....

(Evelyn) says her boyfriend wants her to go to college, as do her parents, but the seriousness of their relationship seems likely to complicate these plans, which is worrying her parents.... Evelyn is adamant, however, that she is not having sex and will wait for marriage for that. She wants to go to college and become a detective, just like her uncle. After college, she plans to get married and have a child, but just one. Evelyn appears determined to achieve her goals. (Christerson, Edwards, & Flory, 2010, pp. 17–19)

CASE ANALYSIS Using What You Know

1. The case presents a number of tensions in Evelyn's life: between her family's goals and her relationship with her boyfriend; within Evelyn herself between her academic and career goals, and her relationship with her boyfriend; and between her father and her mother, who seem to be in agreement in their approach to Evelyn in some ways and in conflict in others. How typical would you say this array of tensions is for adolescents in the United States?
2. How might Evelyn's ethnic and social class identities be influencing her pathway through adolescence?
3. Evelyn has pretty specific goals about her next phases of life: college, marriage, a career, and parenthood. How common is it for early adolescents to have such specific future-oriented goals? How likely are Evelyn's goals to change in the next 5 years?

At this point in our discussion of life stages, we depart again from Erikson's conceptualization. In psychosocial theory, Erikson viewed adolescence as a single stage, unified by the resolution of the central conflict of identity versus identity confusion. Erikson's approach attempted to address the tasks and needs of children and youth ranging in age from about 11 to 21 years within one developmental stage. Based on our own research on adolescence and our assessment of the research literature, we have identified two distinct periods of psychosocial development during these years—early adolescence (12 to 18 years) and later adolescence (18 to 24 years). This chapter discusses the stage of early adolescence; chapter 10 discusses later adolescence.

Early adolescence begins with the onset of puberty and ends roughly at age 18. This stage is characterized by rapid physical changes, significant cognitive and emotional maturation, newly energized sexual interests, and a heightened sensitivity to peer relations. We have called the psychosocial crisis of this stage **group identity** versus **alienation**. Later adolescence begins at approximately age 18 and continues for about 6 years. This stage is characterized by new advances in the establishment of autonomy from the family and the development of a personal identity. The psychosocial crisis of this period is **individual identity** versus **identity confusion**.

The elaboration of adolescence into two stages is closely tied to social and historical changes. At the beginning of the 20th century in the United States, few youths in the 12 to 18 age range were in school; at the turn of the 21st century, almost all of them were. The time between entry into puberty and entry into the self-sustaining roles of adulthood has expanded. In contrast to life 100 years ago, there is a longer period of required education and training, fewer opportunities to enter the full-time labor force without a high school education, laws restricting the employment of children under the age of 16, and a workplace that requires more advanced technical, representational, and interpersonal skills for success. At the same time, occupational choices are much more diverse, and the process of selecting a career path has become increasingly difficult. Young people reach the biological capacity to reproduce and the physical stature of an adult at an earlier age, but they do not yet have fully mature brain development or the education, skills, training, or sense of purpose to create a sustainable independent life. For adolescents, the challenge and the joy of the period is to construct a sense of self that is at once connected to meaningful individuals and groups and, at the same time, authentic and autonomous. Adolescence is a thrilling time of life, a time of lasting memories and first experiences. Young people emerge into a wider, more varied social environment. Their social relationships take on a new intensity and complexity. New and more intricate thoughts are possible, accompanied by new insights about the self as well as the physical, social, and political environments. Many adolescents experience new levels of emotional intensity, including positive feelings such as romantic sentiments, sexual desires, tenderness, loyalty, and spirituality, as well as the negative emotions of depression, anxiety, jealousy, hatred, and rage.

Early adolescence is a period of transition from the relatively weak and protected status of childhood to a more equal position in relation to adults and authority figures. In some cases, as adolescents strive to express their views and preferences, they are met with a strong resistance by adults who still treat teens as if they were young children who are not mature enough to make important decisions. In response to overbearing, harsh, or neglectful adult authorities, adolescents may display anger, rebellion, or depression. They may engage in risky behaviors, including self-harm and harming others. These are the problems that the media, television, and movies tend to highlight.

However, this is not an accurate portrayal of most teens. According to a special report by *U.S. News and World Report*, "adolescents now are less likely than their parents were to smoke, do hard drugs, get pregnant, commit violent crimes, . . . and drive drunk" (Baxter, 2009). Subsequent studies of adolescent risk behaviors support this trend. This group of teens, born beginning in the mid-1990s and sometimes referred to as "Generation Z," is described as conscientious and hardworking (Williams, 2015). In fact, some authors refer to the current generation of adolescents as conservative, even boring (Parker-Pope, 2012). Given a supportive environment in which their parents and other adults are able to balance autonomy-granting and warmth, most young people make important new strides toward maturity during this time. They reach new levels of mastery and a new appreciation of their interdependence with family, friends, community, and culture. ●

Developmental Tasks

Physical Maturation

OBJECTIVE 1 Describe the patterns of physical maturation during puberty for female and male adolescents, and analyze the impact of early and late maturing on self-concept and social relationships.

Coming on the heels of a period of gradual but steady physical development in middle childhood, early adolescence is marked by rapid physical changes, including a height spurt, maturation of the reproductive system, appearance of **secondary sex characteristics**, increased muscle strength, and the redistribution of body weight. At the same time, the brain continues to develop, with changes that increase emotionality, modify memory, and gradually improve connections among areas of the brain that regulate emotion, impulse control, and judgment (Mascarelli, 2012). Variability in the rate and sequence of development is well documented (Brooks-Gunn & Reiter, 1990; Tanner, 1990). The time from the appearance of breast buds to full maturity may range from 1 to 6 years for girls; the male genitalia may take from 2 to 5 years to reach adult size. These individual differences in maturation suggest that during early adolescence, the chronological peer group is biologically far more diverse than it was during early and middle childhood.

Puberty refers to the time in development when a person becomes able to reproduce. However, the changes associated with puberty are quite diverse. Puberty encompasses a group of interrelated neurological and endocrinological changes that influence brain development, changes in sexual maturation, cycles and levels of hormone production, and physical growth. Puberty starts when the hypothalamus begins releasing a hormone called gonadotropin-releasing hormone (GnRH). GnRH then signals the pituitary gland to release two more hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—to start sexual development. This system—the hypothalamus, pituitary gland, and the gonads, often referred to as the HPG axis—is responsible for the production and regulation of the sex hormones that result in the growth and maturation of the reproductive organs (NICHD, 2013). The hypothalamus and pituitary glands are also linked to the adrenal gland (the HPA axis) which controls reactions to stress, regulates digestion, and influences the immune system, mood, energy use, and the sleep-wake cycle (see the **Applying Theory and Research to Life** box about changes in the sleep needs of adolescents). The HPA axis establishes a feedback system that integrates the brain, glands, and hormones to support adaptation. During adolescence, both the HPG axis and the HPA axis are emerging into new patterns of regulation and growth.

There is a great deal of individual variation in the timing, rate of change, and coordination of these changes. Some changes, such as the maturation of the adrenal glands, occur very early, at around ages 6 to 9, and some changes, such as growth in height, can continue well into the late teens and 20s. The term **pubertal status** refers to the extent to which physical changes associated with puberty have taken place, from the very earliest signs of physical development to full sexual and physical maturation. Thus, adolescents of the same chronological age may be at quite different points in their pubertal status. Thus, from a psychosocial perspective, one must think of pubertal development as a gradual transformation in which internal states and external appearance are coordinated with social expectations and a changing self-image (Dorn, Dahl, Woodward, & Biro, 2006).

Adaptation at puberty requires an integration of biological, psychological, and social changes. A young person may be responding to noticeable physical changes, such as a height spurt or the growth of pubic hair, or less readily observable biological changes in hormone production associated with new levels of arousal and emotionality. Psychological changes may be due to chronological age as well as physical changes, since some important societal changes are linked to age rather than to pubertal status. For example, many children make a school transition into sixth or seventh grade at ages 11 or 12, leading to new status, a new sense of responsibilities, and new expectations for school performance. Some responses to puberty are cued by the way other people, including parents, teachers, siblings, and peers, respond to a child whose physical appearance has changed.

In many cultures, **rites of passage**, ceremonies that mark important transitions, occur with entry into puberty, giving the young person new roles and new status within the community. In the United States, many students consider getting their driver's license as a kind of rite of passage—a societal recognition of a new level of autonomy and responsibility. Some responses to puberty have to do with the timing of these changes—whether pubertal changes are perceived to be early, on time, or late in relation to their peers. Thus, puberty is not one event, but a *biopsychosocial* transition that takes on meaning in the context of a child's culture and community.

APPLYING THEORY AND RESEARCH TO LIFE

Sleep Loss in Adolescence

Along with many changes in physical stature and appearance, puberty brings changes in sleep patterns. Research finds that when allowed to sleep as long as they wished, adolescents would sleep about 9 hours. However, as they get older, the quality of the sleep changes, with less time spent in deep sleep, leaving adolescents more tired during the day even when they get the same amount of sleep as younger children (Campbell, Grimm, de Bied, & Feinberg, 2012). In actuality, as adolescents make the transition to high school, they get less sleep than younger children, leaving them more tired and more likely to fall asleep during the day. The majority of 17-year-olds get less than 7 hours of sleep a night (Weintraub, 2016).

The study of sleep and its relation to psychosocial outcomes is a growing field. Questions of interest include how the biological changes of puberty contribute to changes in sleep quality, sociocultural factors that contribute to sleep deprivation, and the impact of sleep habits on cognition and memory, obesity, moodiness, self-esteem, depression, risky health behaviors, and school achievement (Johnson, 2004; Malone, 2011). A combination of societal and biological factors contributes to sleep deprivation in adolescence. Middle school tends to start earlier than elementary school, and high school starts earlier still. Many adolescents are in activities that involve before-school preparation. In many communities, bus schedules determine earlier wake times for older students. Adolescents are likely to stay up late on school nights doing homework, talking with friends, using the computer, or watching television. Some adolescents have jobs at restaurants and stores where they stay until closing time.

The family environment has also been studied as a factor that influences sleep time. For younger children ages 5 through 11, parental warmth is associated with more hours of sleep during the weekdays. However, for older children in the age range 12 to 19, those adolescents whose families had stricter rules actually got more sleep (Adam, Snell, & Pendry, 2007).

In addition to these contextual factors, the natural biorhythm for adolescents shifts toward a preference for a later sleep phase. In comparison with younger children, who sleep about the same amount during the weekdays as on weekends, adolescents tend to sleep much later on the weekends (Williams, Zimmerman, & Bell, 2013). When they have a choice, as on the weekends, older adolescents stay up later at night, when they feel alert and energized, and sleep later in the morning. This shift is tied to pubertal status; those teens who are in a more advanced pubertal status show a greater tendency toward this delay and a greater difference between weekend and weekday sleep (Laberge et al., 2001).

In a longitudinal study of more than 2,000 children, the amount of sleep that children said they got on a typical school night was tracked for 3 years, in sixth, seventh, and eighth grades (Fredriksen, Rhodes, Reddy, & Way, 2004). The amount of sleep for both boys and girls declined from sixth to eighth grade. In the sixth grade, children who got fewer hours of sleep also had lower self-esteem, lower grades, and more depressive symptoms. Those students who experienced the greatest decline in hours of sleep over the 3 years also showed greater increases in depressive symptoms and lower self-esteem by eighth grade. Other national studies support the association between insufficient sleep and a range of risky health behaviors, lack of physical activity, and obesity (McKnight-Eily et al., 2011).

Increasing school start time to 8:30 a.m. or later has been shown to have a benefit. In a study of over 9,000 students in eight public high schools, researchers found the following benefits: better attendance and less tardiness, fewer students falling asleep during class, better academic performance in classes and on state and national achievement tests, and fewer teens involved in car crashes (Wahlstrom et al., 2014; Weintraub, 2016). What is more, students and teachers report that with a later start time comes a change in atmosphere in classrooms and in the school—less moodiness, fewer conflicts, more enthusiastic class participation, which mean happier teachers as well as students. Despite many sources of resistance to a later start time, a number of schools around the country have shifted their schedules and are reporting noticeable benefits. To learn more visit the advocacy website Start Schools Later at http://www.startschoollater.net/success-stories.html.

Critical Thinking Questions

1. Analyze how biological maturation and the social environment interact to alter the amount of sleep adolescents get.
2. Evaluate the implications of not getting enough sleep for adolescents' academic and social life.
3. Hypothesize about how learning and academic performance are influenced by sleep. What might be happening while a person sleeps that contributes to learning?

The degree to which one's body matches the socially valued body build of the culture influences social acceptance by peers and adults. This match between body shape and cultural values also influences the future course of psychosocial development. The European American culture gives self-esteem advantages to muscular, well-developed boys and petite, shapely girls. In contrast, it detracts from the self-esteem of thin, gangly boys, underdeveloped girls, and overweight boys and girls. Changes in body size and shape at puberty can bring advantages or disadvantages, depending on the context (see the case study on Simone Biles).

— CASE STUDY Simone Biles: Three Time World All-Around Gymnastics Champion —

Simone Biles was born on March 14, 1997, in Columbus, Ohio. Her mother struggled with alcohol and drug abuse, so at the age of three, she and her little sister went to live with their grandparents, Nellie and Ron Biles, whom she considers her mom and dad. They live in Spring, Texas.

At the age of 6, Simone was on a field trip with her childcare program. They visited a gym where she watched students learning gymnastics. She began to imitate their moves, and the coach was so impressed that she wrote Simone's parents encouraging them to enroll her in their program. From that point on, she was devoted to gymnastics.

When she graduated from eighth grade, Simone made the decision to be homeschooled so that she could maintain her rigorous workout schedule. Now she devotes 30 hours a week to training and practice.

Simone is a tough, serious, determined athlete. Her mother says she has been a resilient survivor who took control of her life, even at a very young age. At 4′9″ she is a powerful and vivacious competitor. She attributes much of her determination to her mother: "She always told me that although I am small, that doesn't limit my power or define me. For me, I don't think about size—I focus more on being powerful and confident" (Wallace, 2016).

In 2013, at the age of 16, Simone was the world all-around, floor exercise, and vault champion. She was named the 2014 Women's Sports Foundation's individual Sportswoman of the Year. She has won 10 world gold medals, the most in women's gymnastics history. In 2016, as a member of the U.S. Women's Olympic Gymnastics Team, she won four individual gold medals and one bronze medal (usagym.org, 2016).

But her mother, Nellie, says despite the championships, fans, requests for endorsements, and celebrity status, "at home, she's just a teenager who requested a belly ring after her first world title in 2013. [She's] the daughter whose chores include feeding the family's four dogs. The girl who better be at her seat for Sunday dinner regardless of whatever time zone she may have been in the day before" (Graves, 2015).

If you are interested in seeing Simone Biles in action, visit the YouTube videos of her floor exercises at the 2016 Pacific Rim championship competition and the Rio Olympic Games.

CASE ANALYSIS Using What You Know

1. Explain how the case illustrates the interactions among the biological, psychological, and societal systems in supporting unusual ability.
2. Apply what you know about physical development at puberty to the training of a gymnast from childhood into early adolescence. How might this training promote athletic ability and physical health? How might such training create health risks for adolescent girls?
3. You might think of Simone Biles as resilient. How do her personal characteristics and her support system contribute to her ability to thrive?
4. Think about Simone's decision to be home schooled for high school so she could devote herself more intensively to gymnastics training. What factors should a family take into account when determining whether to encourage a young person to follow an alternative educational path in order to pursue a special talent or ability?

Signposts of Puberty for Girls

The following changes are part of the normal pubertal transition for girls. The timing and sequence of these changes are variable, so any chart or table you may encounter about pubertal sequences should be viewed with caution. In general, if none of these signs of puberty are observed by age 13, girls are advised to see a pediatrician (HealthyChildren.org, 2015).

Breast Development. Breast development is typically the first of the secondary sex characteristics to be observed. Recent studies find that the average first sign of breast development (often referred to as "breast buds") is age 8.8 for African American girls, 9.3 for Hispanic girls, and 9.7 for Anglo, non-Hispanic girls (Herman-Geddes, 2013). Generally it takes from 3 to 5 years for breasts to reach their adult size and shape. The rate at which breasts mature and reach adult size and shape varies greatly from one girl to the next. The age at which breast development begins is not related to their adult size (Center for Young Women's Health, 2016).

Pubic Hair. Pubic hair begins to grow shortly after the beginning of breast development, around the age of 8 to 10. For some girls, pubic hair growth precedes breast development. Pubic hair

Olympic champion Simone Biles performing on the balance beam. At 4 foot 9 inches, she dominates her sport.

first appears right around the genital area and then spreads to form an inverted triangle.

Growth Spurt. The growth spurt, including an increase in the rate of growth in height, weight gain, changes in muscle mass, and changes in the distribution of body fat, typically begins about 1 year after the start of puberty. Girls may grow an average of 3.5 inches a year, reaching their adult height at around age 14 or 15. As a result of these changes, a girl's body typically changes to the "hourglass" shape with curves at the breast, hips, and bottom.

Menarche. The first menstrual period usually occurs about 1 ½ to 2 years after the beginning of puberty. A national study reported that the average age at menarche was 11.5 for African American girls and 12.1 for non-Hispanic Anglo girls (Herman-Geddes, 2013). Menarche is often irregular at first, with cycles ranging from 24 to 45 days. After a few years, the cycles become shorter and more regular. Early cycles may occur without ovulation, but the earlier the onset of menarche, the more likely the cycles will include ovulation (American Academy of Pediatrics, 2006). Many young girls wonder how soon they might be able to get pregnant once they begin to menstruate. The answer to this question is not entirely known and differs from one girl to the next.

Underarm Hair, Increased Oil and Sweat Gland Production. Underarm hair appears about 2 years after the growth of pubic hair. At about the same time there is an increase in oil and sweat gland production resulting in a new probability of acne.

Reactions to Breast Development and Menarche

For girls, two of the most noticeable events of puberty are the development of breast buds and the onset of the menstrual cycle (menarche). The trend toward earlier breast development has parents and mental health experts concerned about the compression of childhood. Eight-year-old girls with breasts are still emotionally and cognitively like their undeveloped 8-year-old peers. Their physical development may result in new expectations for more mature behavior and new sexualized attention from older boys.

Menarche is a comparatively late event in a girl's pubertal development. Breast development and the growth of pubic hair are earlier evidence of pubertal growth and may provide the signal that a conversation about menarche is in order. Although most girls are prepared by their mothers for menstruation, the topic is often handled as a matter of hygiene rather than as a sexual transition. Many girls do not understand the relation of menstruation to reproduction. They simply accept their monthly periods as another sign of their femininity. The process of learning about menarche may be somewhat more anxiety producing for girls who are not living with their mothers or with a female caregiver. In a qualitative study of girls who were living without their mothers, the girls were often embarrassed to ask questions of their fathers and experienced more distress around this issue if they did not have access to a woman who could answer their questions (Kalman, 2003). This has special implications for the health of girls who may be separated from their mothers due to maternal death, war, or imprisonment.

Most girls seem to react to menstruation with a mix of positive and negative feelings. The positive feelings reflect their pride in maturing and the confirmation of their womanliness. The negative feelings reflect the inconvenience, unpleasant symptoms, and the possible embarrassment of menstruation (Brooks-Gunn & Reiter, 1990). Girls rarely tell their male peers or their fathers about the onset of menarche, but they do discuss it with their female friends and their mothers. Negative feelings are especially likely if a girl matures early, at age 9 or 10. In a retrospective study involving more than 1,500 Chinese American junior high school girls, students were asked about their knowledge and attitudes about menarche and their emotional responses to their first menstruation. Although 85 percent reported feeling annoyed and embarrassed by their first menstruation, about 66 percent also reported positive feelings, especially feeling more grown up. The more adequate their preparation for menarche and the more they saw menarche as a natural, healthy event, the more positive were their emotional responses (Tang, Yeung, & Lee, 2003).

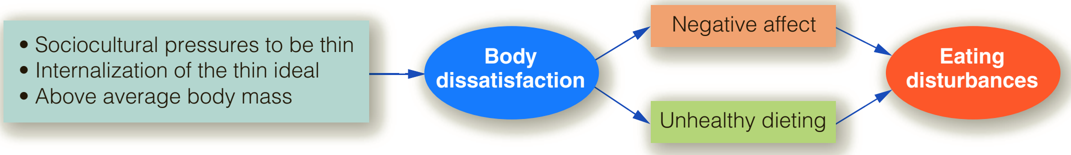
Concerns About Obesity

The greatest concern that adolescent girls express about their bodies is the perception that they are too fat. This concern about **obesity** is that it results in peer rejection from both boys and girls.

Lisa is a seventh grader who attends a White, upper-middle-class middle school. She is clearly overweight. As a newcomer to her school, she found that her weight was the major factor in determining her social and academic experiences.

> At first I thought if I got good grades and tried to fit in it wouldn't matter how I looked. But I still got teased; it didn't make a difference. All the good things about me—like that I was smart—it was just, "You don't fit. You don't look good. You're fat." I felt like I was doing all the good things for no reason. So I just said, "Fine, if it's going to be that way, then I don't care." And I don't try at all anymore. I don't care about school. (Orenstein, 2000, pp. 100–101)

In a review of research on body dissatisfaction and eating disorders, Stice and Shaw (2002) found support for a relationship between body image disturbances and eating disorders (see FIGURE 9.1 ▶). Three factors appear to contribute to **body dissatisfaction** among adolescent girls: social pressures to be thin, an internalized thin ideal body type, and higher than average body mass. Those girls who have higher body dissatisfaction are likely to start dieting and also to experience negative emotional states, especially depression. In a longitudinal study of adolescents in grades 7 through 12, symptoms of depression predicted obesity 1 year later. The link between depression and obesity may be due to a decrease in physical activity, or for some, an increase in hunger eating and weight gain (Goodman & Whitaker, 2002; Needham Epel, Adler, & Kiefe, 2010). The combination of these factors can lead to future eating pathologies. In an attempt to attain a thin ideal and to reduce negative feelings about themselves, many early adolescent girls begin a process of strict and often faddish dieting. This strategy is ill-timed, because their bodies require well-balanced diets and increased caloric intake during the period of rapid growth (Stice & Shaw, 2004).



• Sociocultural pressures to be thin
• Internalization of the thin ideal
• Above average body mass
Body dissatisfaction
Negative affect
Unhealthy dieting
Eating disturbances

FIGURE 9.1 ▶ THE RELATIONSHIP OF BODY IMAGE TO EATING DISTURBANCES

Source: Based on Stice and Shaw, 2002.

Concern about being overweight is linked to the day-to-day experiences girls have with peers at school. Girls who face peer teasing about their body and physical appearance are likely to experience heightened body dissatisfaction and declines in their global feelings of self-worth (Jones & Newman, 2009). Girls who are overweight are more likely to try to lose weight if other girls at their school of similar body type are also trying to lose weight. Girls who are underweight are also more likely to try to lose weight if other underweight girls at their school are trying to lose weight. Even though girls are aware of a broad, cultural ideal about thinness, their own body satisfaction and behavior regarding weight control or weight loss are influenced by what other girls in their immediate social world say and do (Mueller, Pearson, Muller, Frank, & Turner, 2010).

For girls, one of the compounding factors in obesity is that they tend to reduce their activity level with age (Finne, Bucksch, & Lampert, 2011). One longitudinal study monitored common physical activities for children from grades 3 through 10. During grades 6 through 8, those girls who were more advanced in their pubertal status were less active than the girls who were less physically mature (Bradley, McMurray, Harrell, & Deng, 2000).

Signposts of Puberty for Boys

The following changes are part of the normal pubertal transition for boys. As with girls, the timing and sequence of these changes are variable, so any chart or table you may encounter about pubertal sequences should be viewed with caution. In general, if none of these signs of puberty are observed by age 14, boys are advised to see a pediatrician (HealthyChildren.org, 2015).

Testicles and Scrotal Sac. The first signpost of pubertal development for boys is usually an increase in the size of the testicles. The skin of the scrotum is likely to show some reddening and a rougher texture. Evidence from a sample of over 4,000 boys found that on average, the first signs of this pubertal development occurred at ages 9.1 for African American boys, 10.04 for Hispanic boys, and 10.14 for non-Hispanic Anglo boys (Herman-Giddens et al., 2012). The testes produce sperm and testosterone.

Pubic Hair. Pubic hair begins to grow about 1 ¼ years after the start of testicular growth (Herman-Giddens et al., 2012).

Growth Spurt. The growth spurt, which includes changes in height, weight, muscle mass, and body shape, begins about 2 years after the start of puberty and may continue for 2 to 5 years. Most boys stop growing between the ages of 17 and 19, although some continue to grow into their 20s. Growth does not take place at the same rate in all parts of the body. One particular discrepancy is the time lag between the height spurt and the increase in muscle strength. The peak increase in muscle strength usually occurs about 12 to 14 months after the peak height spurt (Brierley, 1993). Eventually, most boys' bodies change to acquire an inverted triangular shape—wider at the shoulders and narrower at the waist and hips.

Growth of the Penis. About 1 year after the testicles begin to enlarge, the penis starts to grow. As the penis grows, boys begin to experience erections. About a year after the penis starts to grow, most boys experience an ejaculation of semen. The semen may not carry sperm right away, but by the time the testes are fully grown, sperm are produced and the boy is fertile.

Change in Voice. At the same time as the penis is growing, a boy's voice is changing. This is caused by the increased size and thickening of the larynx. This is usually accompanied by some cracking or squeaking in the early phase, followed by a deepening in tone.

Facial and Underarm Hair. Body and facial hair begin to be noticeable about 2 years after the beginning growth of pubic hair.

Oil and Sweat Production. The production of oil and sweat glands increases at about the same time as the growth of underarm hair. This can result in acne if the oil clogs skin pores.

Boys' Reactions to the Physical Changes of Puberty

Boys generally welcome the changes involving increased height and muscle mass that bring them closer to adult maturity. Nonetheless, some ambivalence is likely as boys experience the transitions of puberty. On the one hand, a mature physique usually brings well-developed physical skills that are highly valued by peers and adults alike. On the other hand, the period of rapid growth may leave a boy feeling awkward and uncoordinated for a time. For boys, body image dissatisfaction is typically associated with frustration about not looking muscular, strong, or handsome—a concern that is magnified by the lag between the height spurt and the increase in muscle mass (Cohane & Pope, 2000). In a national survey of British teens, dissatisfaction with body image was the third most common worry for boys. Boys expressed concern about being too fat or not attractive enough; a third had been on a diet to improve their body image (Espinoza, 2016).

Spermarche, the production and release of sperm that can be detected in a boy's urine, occurs rather late in the pubertal process

(Dorn et al., 2006). Boys are generally not well prepared by their parents with information on the maturation of their reproductive organs. Specifically, they are not taught about the pattern of gradual genital changes that are likely to occur or about spontaneous ejaculation and may be surprised, scared, or embarrassed by it. The sexual connotation of the event may make it difficult for boys to seek an explanation from their parents. They are left to gain information from friends, or to go online for medical opinions and peer reactions (KidsHealth.org, 2013). For many boys, spontaneous ejaculation provides an important clue to the way in which physical adult sexuality and reproduction are accomplished. The pleasure of the ejaculation and the positive value of the new information that it provides are counterbalanced by a mild anxiety.

A third area of physical development that has psychological and social meaning for boys is the development of secondary sex characteristics, particularly the growth of facial and body hair. In many societies, the equipment and ritual behaviors associated with shaving are closely linked to the masculine gender role. Most boys are eager to express their identification with this role, and will use the slightest evidence of facial hair as an excuse to take razor in hand. The ritual of shaving not only provides some affirmation of the boy's masculinity, but it also allows him an acceptable outlet for his narcissism. As he shaves, it is legitimate for him to gaze at and admire his changing image. In some societies, the ability to grow a mustache or a beard is a sign of one's masculinity. In these cultures, boys cultivate and admire their mustaches or beards as evidence of their enhanced male status. See Table 9.1 for a summary of primary and secondary sex characteristics in boys and girls.

Cultural Contexts of Puberty

The way adolescents react to the physical changes of puberty depends in part on the cultural context (Buzney & DeCaro, 2012). For example, studies of Mexican youth find that girls become somewhat more depressed as they go through puberty, whereas boys experience an improved sense of body image and well-being (Benjet & Hernandez-Guzman, 2002). These gender differences may reflect the greater status and new responsibilities given to male children in Mexican culture, and the new restrictions that apply to female children as they enter puberty in order to protect their chastity.

A report on the reactions of female students in India who were following an undergraduate medical curriculum found that most of these young women said that they were ill prepared for their menarche. About half reported that their emotional reaction to their initial menstruation was panic. The cultural attitude toward menstruation among Indian women is typically one of secrecy and uncleanliness. The cultural transmission of these attitudes from mothers to daughters means that mothers generally try to keep their menstrual experiences hidden and are reluctant to talk to their daughters about it. As a result, menstruation remains a source of anxiety and embarrassment for many (Bharatwaj, 2014).

In another cultural comparison, several studies comparing African American and European American adolescent girls were summarized. In general, African American adolescent girls are more satisfied with their body image and less inclined toward eating disorders than European American girls. Furthermore, early pubertal onset and weight increases were not particularly strong predictors of negative body image and depression among African

Table 9.1 **The Development of Primary and Secondary Sex Characteristics for Girls and Boys**

Girls	Average Age of Occurrence	Boys
Onset of height spurt	10–11	**Growth of testes**
Initial breast development	11	Development of pubic hair
Increased activity of oil and sweat glands (acne can result from clogged glands)	11–12	Increased activity of oil and sweat glands (acne can result from clogged glands)
Development of pubic hair	12	**Growth of penis**
Onset of menarche (age range is 9–17)	12–13	Onset of height spurt
Earliest normal pregnancy	14	Deepening of the voice
Completion of breast development (age range is 13–18)	15–16	**Production of mature spermatozoa** **Nocturnal emissions** Growth of underarm and facial hair
Maturation of skeletal system	17–18	Maturation of skeletal system Development of chest hair

Note: Primary sex characteristics are in boldface type.

The **primary sex characteristics** relate to the development of genitalia and reproductive organs. Secondary sex characteristics are other physical changes associated with puberty, such as body hair or breast development.

American girls, as they are for European American girls (Franko & Streigel-Moore, 2002).

The Secular Growth Trend

A **secular growth trend** is a change over time in the average age at which physical maturation takes place (Godina, 2009). All over the world, changes in hygiene, nutrition, and health care have contributed to an earlier entry into puberty and earlier growth spurt over the past century (Richter, 2006). In the United States, children ages 10 to 14 increased in height by an average of 2 to 3 centimeters every decade from 1900 to 1960. Adult height is not necessarily greater due to this increase; it is simply attained at an earlier age.

Other evidence of a secular trend is the decrease in age for the onset of puberty, including an earlier age for the beginning of breast development in girls and for testicular development for boys (Herman-Geddes, 2013). In addition, average age at menarche has declined. Data reported by Tanner (1990) showed a decrease in the average age at menarche from the 1950s (13.5 to 14 years) to the 1970s (12.5 to 13 years). At present, the mean age at menarche in the United States is 12.1 for white, non-Hispanic girls and 11.2 for African American girls (Buttke, Sircar, & Martin, 2012).

Age at menarche varies among countries and even among socioeconomic groups within a country. Evidence from two rural counties in China illustrates the impact of improved living standards on age at menarche. In a survey of over 12,000 females, age at menarche decreased from an average of 16.5 to 13.7 over an approximate 40-year interval. Improvements were associated with a variety of environmental conditions including reduced pesticide exposure before age at menarche, the source of drinking water, the amount of physical labor the girls were required to perform, and improved nutrition (Graham, Larsen, & Xu, 1999). Researchers in Italy report that Italian girls reach menarche about a quarter year earlier than their mothers' generation. A number of factors were associated with age at menarche in the Italian sample including the mother's menarcheal age, the region where the parents were born, family size, and the girl's body mass index (Rigon et al., 2010).

What is the relevance of the secular trend for understanding the development of contemporary adolescents in post-industrialized societies? Modern adolescents experience a mismatch between the biological and the societal systems as they make their transition from childhood to adulthood. Reproductive capacity and physical adult stature occur at a younger age than at the turn of the 20th century, but full engagement in the adult society requires more training, education, and complex preparation than in the past. Thus, adolescence is prolonged, with more time to experience the risks of unwanted pregnancy and the sense of being in a marginal social status. At the same time, many adolescents experience a longer "protected" status as students and legal minors, with delayed expectations for self-sufficiency and enactment of adult roles.

The concept of the secular trend alerts us to the importance of the psychosocial context of physical development. Because the period of reproductive capacity starts earlier than it did 50 years ago, young people must cope with special challenges in the expression and regulation of their sexual impulses. One consequence of the earlier onset of puberty is that adolescents may find themselves in potentially high-risk situations at a relatively young age, a reality that has become a major contemporary health and mental health concern (Weir, 2016).

Individual Differences in the Timing and Rate of Change

The age at onset of puberty and the rate of change in physical maturation vary. Children of the same chronological age can be at very different points in their pubertal maturation. Whereas individual differences in the onset of puberty are to be expected, **precocious puberty**, that is evidence of pubertal maturation before the age of 8 for girls or before the age of 9 for boys, may be an indication of a more serious medical problem (Boyse & Phelps, 2012).

The Impact of Pubertal Timing for Boys. Early and late maturing and the length of time it takes for a child's body to achieve adult physical and reproductive status have psychological and social consequences for both boys and girls. Research carried out in the 1950s and 1960s found that boys who matured early

By grade 8, the physical diversity of the peer group is quite noticeable. Differences in height, weight, and body shape have implications for popularity, leadership, athletic success, and self-confidence.

Phil Boorman/Cultura/Getty Images

experienced positive consequences, including greater opportunities for leadership and social status, and as a result, they had higher self-esteem (Clausen, 1975; Mussen & Jones, 1957). A similar advantage for early maturation for fifth- and sixth-grade boys was reported in the early 1990s. The boys who were more physically mature described more positive daily emotions, better attention, and feelings of being strong (Richards & Larson, 1993). In contrast to the early maturing boys, late maturing boys express greater body dissatisfaction, especially at the start of high school (de Guzman & Nishina, 2014). In a comparison of early maturing girls and boys, the early maturing boys reported less stress in opposite-sex relationships than the girls and less depression associated with these early other-sex relationships (Llewelyn, Rudolph, & Roisman, 2012).

Several explanations have been offered to account for the advantages of early maturing for boys. Early maturing boys are likely to be given increased responsibility by their parents and teachers. They are generally more satisfied with their bodies, feel more positive about being boys, and are likely to be more involved in school activities by the 10th grade than are late-maturing boys. Early maturing boys are likely to have more advantages in competitive sports, especially those that rely on height and muscle strength, and are likely to have advantages in peer popularity. In contrast, boys who mature later than their age-mates may experience psychological stress and develop a negative self-image. Late-maturing boys are treated as if they were younger than they really are. They may become isolated from their peers or behave in a silly, childish manner to gain attention.

In contrast to this picture of psychological and social advantages, other research tells a somewhat different story of the consequences of early maturing for boys, especially those who mature in grade 7 or before. Boys who experience early puberty are at greatest risk for externalizing problems (Marceau, Ram, Houts, Grimm, & Susman, 2011; Science Daily 2010). These early maturing boys have more hostile feelings, greater levels of anxiety and depression, more problems with drug and alcohol use, and more deviant activities and problems in school than boys who mature at a later age. The association of early maturation and heightened rates of violent and nonviolent delinquent behavior has been observed for African American, Mexican American, and European American youth (Cota-Robles, Neiss, & Rowe, 2002). In a longitudinal study of over 3,000 South African children born in the early 1990s, early maturing boys and girls were found to be more involved in high-risk behaviors such as smoking, experimenting with drugs, and sexual behavior than their less physically mature age-mates (Richter, 2006).

How can we account for these differences? Is early maturing a benefit or a risk for boys? Explanations for the impact of early maturation for boys vary. One explanation is that we are looking at a cohort effect. Maturing early in the 1950s may have been a more positive experience, whereas maturing early in the 1990s may expose adolescent boys to more stressors. Another explanation is that in today's society, physical maturation at age 12 and earlier converges with other stressful life events, especially school transitions, disruption of the peer network, more challenging expectations for school performance, and the related risk of failure. More stressful life events coupled with the pubertal transition increase uncertainty and may leave boys feeling out of control. The combination of heightened stress reactivity during early puberty and the possible exposure to environmental stressors such as peer violence, school demands, or harsh parenting alter the brain's response to stress-related hormones and increase the boy's anxiety and depression (Holder & Blaustein, 2014).

A third explanation is that boys who mature early have not had time to fully master the tasks of the middle childhood period. This explanation fits especially well for the studies that consider boys who experience puberty both early and quickly. With an early height spurt and a more mature physical appearance, they may be accelerated into situations where they are faced with expectations for a level of self-control, decision making, and leadership for which they are not prepared. They may be likely to spend time in the company of older boys who are also involved in more risky behaviors (Ge, Conger, & Elder, 2001; Ge & Natsuaki, 2009).

These different views of the impact of early maturing may all be correct. For example, it may be true that early maturing boys do experience greater opportunities for leadership and social status. The advantages of an earlier height spurt and related increases in muscle mass and endurance can make a significant difference as boys engage in athletic competitions with their age-mates (Gladwell, 2008). At the same time, because they look older, they may begin to engage in some of the high-risk behaviors of slightly older boys.

The Impact of Pubertal Timing for Girls. The literature on the effect of pubertal timing for girls is more consistent in finding that early pubertal onset is a source of stress (Joinson et al., 2012; Marceau et al., 2011; Weingarden & Renshaw, 2012). Because pubertal changes occur earlier for most girls than for boys, the early maturing girl stands out among all her male and female age-mates. Early onset of breast development is associated with a new surge of gonadal hormones, which may create heightened emotions of depression, self-consciousness, and anxiety (Peper & Dahl, 2013). Early maturing girls are less likely to have been prepared for the onset of menstruation, and they are less likely to have close friends with whom they can discuss it. Early pubertal maturation may result in feelings of social isolation and social anxiety for girls (Blumenthal et al., 2011). Early maturing girls experience higher levels of conflict with their parents and are more likely to report depression and anxiety (Wierson, Long, & Forehand, 1993; Winer, Parent, Forehand, & Breslend, 2016). Early maturing girls are less likely to be physically active than their age mates, are more dissatisfied with their physical appearance, and are especially vulnerable to low self-esteem (Cumming et al., 2012; Williams & Currie, 2000).

There is some evidence that early maturing girls earn lower grades and lower scores on academic achievement tests. They are also more likely to be identified as having behavior problems in school. Early maturing girls start dating earlier and perceive themselves as more popular with boys than do late maturing girls. Some studies report that early maturing girls are more likely to engage in high-risk, promiscuous sexual behavior. They are also more likely to be exposed to sexual harassment (Skoog & Ozdemir, 2016). Taken by itself, the timing of the transition to puberty is not a strong predictor of a girl's emotional well-being. Rather, this timing interacts with other contextual factors, including school transition, family conflict, peer acceptance, and unwanted sexual advances, to influence how girls construct the meaning of this physical transition (Booth, Johnson, Granger, Crouter, & McHale, 2003; Skoog, 2013).

Many books and websites emphasize the important role for parents in talking to their children about their physical, psychological, and social experiences as they go through puberty. Given the evidence about the hereditary influences on pubertal timing, it could be very helpful for parents to talk to their children about what it was like when they experienced these transitions. It is also important to be proactive, recognizing the early signs of puberty that may arise at ages 8 to 10, to help young people feel prepared for subsequent changes.

However, there are important limitations to this advice. First, not all children arrive at puberty in the context of a warm, sensitive parent–child relationship. Some children have been exposed to harsh or neglectful parenting in toddlerhood and early childhood, thus leaving them more vulnerable or reactive to the stressors of puberty. For these children, the opportunity to find support and encouragement in conversations with parents is unlikely; they need to have access to other supportive adults who can help them navigate this important transition. Second, as puberty progresses, parent support may not have the stress-buffering benefits that it had at earlier ages (Hostinar, 2015). There may be important benefits to forming supportive peer relationships and adult mentor relationships that can provide reassurance and positive regard while helping to strengthen adolescents' coping strategies during times of stress and uncertainty.

Romantic and Sexual Relationships

OBJECTIVE 2 Summarize the development of romantic and sexual relationships, and evaluate the factors that influence the transition to first intercourse, the formation of a sexual orientation, and pregnancy and parenthood in early adolescence.

During adolescence, romantic relationships, sexual fantasies, and sexual behaviors increase, partly as a result of biological changes and partly as a result of social, cultural, and historical contexts. Early in puberty, the HPG axis is reactivated leading to increases in the production of gonadal hormones, testosterone, and estradiol (a form of estrogen). The adrenal gland generates increases in DHEA and other hormones linked to the growth of pubic hair, body odor, acne, and pre-pubertal growth (Peper & Dahl, 2013; Shirtcliff, Dahl, & Pollack, 2009). The amount of these hormones that is absorbed in the blood reaches a peak between the ages of 10 and 12—a time when both boys and girls begin to be aware of sexual feelings toward others (Herdt & McClintock, 2000). Whereas the early onset of these feelings may be triggered by biological factors, the way they are expressed depends largely on socialization and cultural factors.

The Transition into Sexualized Relationships

Most young people are involved in a variety of romantic relationships during adolescence, including dating, feelings of tenderness and love, and deepening commitments (Temple-Smith, Moore, & Rosenthal, 2016). Components of both gender identity and sexual orientation, which have implications for the young person's motivation and opportunities for sexualized relationships, are formulated during this period of life. Some adolescents are reticent about sexual behavior. Others are sexually permissive and regularly active in sex play, from petting to intercourse. The manner in which early adolescents think about sexual relationships varies. Some are preoccupied by thoughts of very romantic, idealized relationships. They can become infatuated with rock stars, athletes, movie stars, or other sex symbols. Some have crushes on boys or girls in their school or neighborhood, and still others have obsessions with sexual material but do not have any tender or caring relationships with peers.

Sexual desire can be thought of as having at least two faces: sexual arousal and sexual motivation. Sexual arousal refers to the way a person's body and thoughts are stimulated by sexual fantasies, images, and reactions to others. Sexual motivation refers to a person's interest in initiating sexual behaviors (Diamond &

Savin-Williams, 2009). Adolescents do not arrive at puberty as complete novices in sexual desire. According to psychoanalytic theory, children are sexual beings from infancy, using and exploring their bodies in order to experience physical pleasures. Children experience erotic activity before puberty, including self-stimulation, viewing sexually explicit media, or experimenting with sexual role-playing with peers. Early adolescents' sexual interests reflect a system that has been running at a low level and is now energized by new hormonal levels, maturing sexual features, and changing cultural views about the acceptability of sexual behavior. As a result, adolescents begin to think of themselves as sexual, develop scripts and schemes for how to act sexually with others, and begin to formulate ideas about the qualities of people whom they find sexually attractive.

Dating. Pubertal changes may increase a young person's interest in sexual ideation and arousal, but the timing and rituals or *script* of dating depend on the norms of the peer group and the community. Most teens today do not use the term "dating." They use expressions like "seeing someone," "getting together," or "going with" someone. Regardless of the way they talk about it, young people learn the art of flirtation, practice how to approach and how to coyly refuse, and learn the rules of engagement between the sexes, which vary from culture to culture and from cohort to cohort. The hallways of a high school may not seem very romantic, but feelings of affection can blossom in the most unexpected places.

Contemporary youth describe a diversity of relationships that may involve sexual activity. Participation in mixed-sex friendship groups typically provides the context for the formation of romantic pairing that becomes more exclusive and less group oriented over time (Connolly, Craig, Goldberg, & Pepler, 2004; Dunphy, 1963). Most sexual activity occurs in the context of close relationships. However, teens also describe having sexual experiences in the context of noncommitted relationships with ex-boyfriends or ex-girlfriends, people they have just met ("hooking up"), friends or acquaintances ("friends with benefits"), and people they just date every once in a while (Connolly & McIsaac, 2011). Both texting and "sexting" are ways that teens use electronic media to initiate and expand their sexualized or romantic feelings. Involvement in romantic relationships increases over the middle school and high school years, and the quality of these relationships becomes increasingly intimate.

One approach to understanding the nature of adolescent dating is to see this social behavior as meeting one or more central life goals, especially identity, intimacy, status, and sexuality (Kelly, Zimmer-Gembeck, & Boislard, 2012). Identity goals reflect a need for self-acceptance, self-assurance, and the ability to express and maintain personal interests. Teens use the concept of "respect" to emphasize the importance of identity in a relationship. Intimacy refers to the desired for committed, exclusive relationships that support emotional closeness, disclosure, and security. Status focuses on social validation, social striving, and support for a desirable group identity. Teens know that their peers are making judgments about their relationships; their choice of a partner can be a source of pride or embarrassment in the peer context. Sex may refer to opportunities to satisfy sexual urges, to enjoy sexual pleasure, or to experience various forms of sexual exploration and experimentation. Satisfaction in dating can be evaluated by how well the relationship allows a young person to achieve each of these goals.

First Intercourse. The sexual transition at first intercourse may take place in very different contexts. It may be a planned event or an unplanned impulse, often combined with alcohol use or a drug high. The sexual encounter may be viewed as a marker of independence or as an act of rebellion against and defiance of the family. It may take place in the context of an ongoing close relationship or as part of a casual encounter. Usually, the earlier the transition into sexual activity and intercourse, the more likely the act is to be part of a profile of high-risk behaviors, including alcohol use, drug use, and delinquent activity. For girls 14 years old and younger, 27 percent said that they did not want their first sexual experience. For many of these young teens, their first sexual experience was a result of being sexually assaulted. The later the transition, the more likely it is to be seen as a marker of the transition into adulthood or as a planned aspect of the deepening commitment to an ongoing relationship (Terry-Humen, Manlove, & Cottingham, 2006).

A national survey of students in grades 9 through 12 conducted in 2013 reported that 47 percent of students surveyed had had sexual intercourse. The prevalence of sexual intercourse increased with grade level, such that by 12th grade, 64 percent were sexually experienced, and 49 percent were currently sexually active. Eleventh grade seems to be the tipping point, by which time more than half the students (51 percent) are sexually experienced (Kann et al., 2014).

Boys report being sexually active at younger ages than girls. Boys are aware of sexual urges and

Hero Images/Superstock

Romance begins to stir in the halls of the high school.

interests at a younger age than girls; they report more frequent sexual arousal than girls; and boys report that their sexual feelings are more distracting than girls report (Diamond & Savin-Williams, 2009). Eight percent of boys and 3 percent of girls reported having sexual intercourse before age 13. Among ninth graders, 9 percent of boys and 4 percent of girls said they had already had sex with four or more partners; by 12th grade this had increased to 21 percent of girls and 26 percent of boys (Kann et al., 2014).

Roughly one third of U.S. adolescents have not had sexual intercourse by 12th grade. This does not mean that they are sexually inexperienced. In a study of 11- and 12-year-old girls, 46 percent of 12-year-old girls had hugged a boy. Other intimate behaviors that were reported at this age were spending time alone with a boy or girl, holding hands, and kissing (Hipwell, Keenan, Loeber, & Battista, 2010). It is not uncommon for teens to experience oral sex, even if they have not had sexual intercourse. Among 15 to 19 year olds, close to 50 percent of males and females have had oral sex (Copen, Changra, & Martinez, 2012).

There are at least five reasons why data regarding entry into sexual activity and age at first intercourse must be interpreted with caution (Diamond & Savin-Williams, 2009). First, teens who are uncomfortable or whose parents are uncomfortable participating in research on this topic will not be included. Second, studies rarely include questions about same-sex sexual activity that might be comparable to first intercourse. Third, the reporting is retrospective (i.e., asking adolescents to think back to when they first engaged in sexual activities) and thus is vulnerable to inconsistencies and memory errors. Fourth, cultural and social contexts may influence reporting. It may be socially desirable to exaggerate one's sexual experiences in some communities and socially responsible to conceal one's sexual experience in others. Finally, most studies focus on individual reports and do not gather data to confirm reported sexual experiences by participating partners.

Factors Affecting the Initiation of Sexual Intercourse

The unfolding of sexual behavior in adolescence includes many components such as feelings of arousal or sexual excitement, sexual fantasies, self-stimulation, awareness of a desired object, feelings about being a desirable partner, and intentions to abstain or engage in sexual activities. Although all of these aspects of sexual maturation are relevant to the eventual experiences of partnered sexual intercourse, many of them have not been documented in a systematic way (Fortenberry, 2013). In contrast, most of the research focuses on the experience of sexual intercourse, which typically occurs after many of these more private experiences arise. FIGURE 9.2 ▶ provides a useful model for thinking about factors that influence the transition to sexual intercourse in early adolescence (Udry, 1990; Udry & Billy 1987). In that model, three dimensions account for the adolescent's initiation of sexual activity: *motivation*, *social controls*, and *attractiveness*.

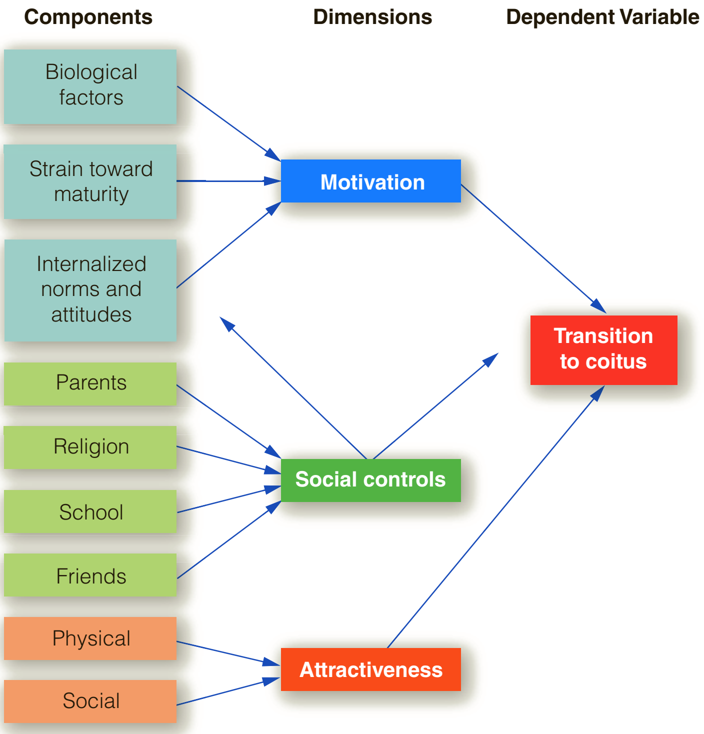

FIGURE 9.2 ▶ A MODEL OF THE TRANSITION TO FIRST COITUS IN EARLY ADOLESCENCE

Source: Adapted from Udry & Billy, 1987.

The first dimension, **sexual motivation**, includes the biologically organized drives associated with sexual arousal and sexual pleasure, as well as a range of social motives such as achieving new levels of intimacy in a relationship, pleasing one's partner, impressing one's peers, gaining sexual experience, or preventing conflict or dissolution by providing sexual satisfaction (Impett & Tolman, 2006). Some sexual motives can be considered approach motives in that sexual activity is viewed as a way of achieving a positive outcome, like increasing one's physical pleasure or enhancing intimacy. Some sexual motives can be considered avoidance motives if sexual activity is viewed as preventing a negative outcome, like reducing conflict in a relationship. In a study of positive sexual motives among ninth graders, females valued achieving intimacy more than males, and males valued sexual pleasure more than females. Adolescents expected that sexual experience would most likely satisfy motives for sexual pleasure, then for intimacy, and least for social status. Those ninth graders who were sexually active had greater expectations that sexual activity would result in greater intimacy in the relationship than those who were not sexually active (Ott, Millstein, Ofner, & Halpern-Felsher, 2006).

The second dimension, **social controls**, refers to the normative environment in which sexual activity is embedded. According to the model, these controls are a product of parental socialization and practices, school achievement and educational aspirations, and the attitudes and sexual experiences of friends. We have added the important influence of religious beliefs and values to the model's list of social controls.

For girls, various social controls—including parents, school achievement, friends' attitudes and behaviors, and religious values—all play an important part in predicting sexual intercourse. A girl's decision to become sexually active is influenced by her own self-esteem, her personal aspirations, her parents' values, her educational expectations, and the capacity of her parents to exercise appropriate control over her social and school activities and the norms of her peer group (Udry, Kovenock, Morris, & van den Berg, 1995).

Parental monitoring and the extent to which adolescents have unsupervised opportunities for sexual activity may be aspects of social controls. Teens who have stronger bonds with their parents and whose friends have less permissive views about sexual behavior are more likely to delay their transition into sexual intercourse (L'Engle, & Jackson, 2008). Even for those who live in low-income, chaotic neighborhoods, teens whose parents establish clear family routines and who know about their child's friends, their activities, and where they are when they are away from home have a later entry into sexual intercourse (Roche & Leventhal, 2009). In contrast to the children who have close, supportive bonds with their parents, some young people arrive at adolescence with a reduced ability to inhibit their impulses. They may be more likely to spend time with peers who encourage sexual adventuring as one of many high-risk behaviors.

The third dimension, **attractiveness**, influences the availability of partners. Attractiveness is defined in part by pubertal maturation, social acceptance or popularity, and also by the local peer environment in which one is judged to be pretty or handsome. Certain features of physical appearance, such as being overweight, or being a late maturing male may result in delayed entry into sexual experience.

Across cultures, boys typically experience a consistent message that being sexual is a valued aspect of the masculine gender identity. In contrast, girls are confronted by conflicting messages about the desirability and risks of being sexually active. These confusing messages operate to increase girls' sensitivity to the social context in which her decisions are made and are likely to delay coitus, even if they do not stifle her sexual desires. A separate reason that the link between hormonal levels and sexual debut is unclear for girls is that for many young girls their early sexual experiences were unwanted.

The Effects of Religious Beliefs on Sexual Behavior

One of the clearest cultural influences on adolescent sexual behavior is religious participation. Adolescents who frequently attend religious services and church-related activities and who value religion as an important aspect of their lives have less permissive attitudes toward premarital sex. They may believe that they should wait until after marriage to engage in sexual intercourse. However, within a religious framework the way adolescents define abstinence can vary from complete sexual denial to sexual activity that stops just short of vaginal intercourse (Uecker, Angotti, & Regenrus, 2008).

An adolescent's attitudes toward premarital sex are shaped by many factors in addition to religious beliefs. By the time young people are making independent decisions about religious participation, they also have opinions on premarital sex. Thus, those young people who have more permissive views on sex may be less likely to attend religious services and may find less satisfaction in religious participation.

As an example of how religious beliefs can affect sexual behavior, the Southern Baptist Church initiated a program that encouraged teens to make a public virginity pledge. Since 1993, more than 2.5 million youth have taken this pledge in which they vow to abstain from sex until marriage. In a study of those who participated in the program, the pledge was found to be most effective in delaying the age of first intercourse when taken by younger teens. It was also more effective for pledge takers who are a minority among their peers. Taking the pledge is then viewed as an act of independent decision making and identity commitment rather than as compliance to peer norms (Bearman & Brueckner, 2001; Martino et al., 2008).

Findings based on the National Longitudinal Study of Adolescent Health suggest that one of the hazards of taking the pledge is that when it is broken, youth are less well prepared to engage in protected sex and are therefore at risk for sexually transmitted diseases. Five years after making their pledge, 82 percent of teens denied having ever made this pledge. Those who had pledged were no different from matched non-pledgers in the percentage who had premarital sex, sexually transmitted diseases, or lifetime sexual partners (Rosenbaum, 2009).

Sexual Orientation

It is not always possible to distinguish sexual behaviors that reflect a form of experimentation and exploration from behaviors that reflect an eventual commitment to a same-sex or bisexual orientation. The language for describing a person's sexual orientation is expanding as the society becomes more aware of sexual diversity and information about sexual orientation becomes more widely available. Table 9.2 provides a brief glossary of terms that refer to alternative sexual orientations. One might assume that sexual orientation begins to take shape in early adolescence, yet research on this point suggests a more differentiated path. Many adolescents are unsure about their sexual orientation even by the end of high school, and others have known since early childhood that they do not fit the heterosexual model.

> Since childhood I felt attraction for both boys and girls,
> but gradually the feelings for girls went away. One day,
> a new guy to my school walked into class and I felt such
> an attraction that I simply knew. (Jordan, 17 years)
> (Hillier et al., 2010)

One's sexual orientation includes an awareness of sexual attraction to others, which may arise in fantasy, while watching videos or movies, observing one's peers, or as an aspect of any private thoughts. Thus, a young person may be aware of a nontraditional sexual orientation well before he or she is ready to engage in sexual activity with a partner. In the Adolescent Health survey, 13 percent of girls and 6 percent of boys reported that they had experienced same-sex attractions or same-sex relationships. However, only a subset of these youth identified as having a non-heterosexual sexual orientation. Teens who have same-sex sexual experiences may still identify as heterosexual; many teens who have self-identified as gay or lesbian have also had cross-sex

Table 9.2 A Brief Glossary of Terms and Definitions Related to Sexual Orientation

Term	Definition
Asexual	A person who is not interested in sex and may not experience sexual attraction, but who still has emotional bonds with others. Asexuality is not the same as celibacy or abstinence.
Bisexual	A person who is sexually and emotionally attracted to people of both sexes.
Gay	A person whose primary emotional and sexual attraction is toward people of the same sex. Commonly applied to men, although women sometimes use the term as well.
Heterosexual	A person whose primary emotional and sexual attraction is toward people of the opposite sex. Heterosexuals are sometimes called "straight."
Lesbian	A woman whose primary emotional and sexual attraction is toward other women.
Pansexual	A person whose emotional and sexual attractions are fluid and open to people of all types of sexual orientation and gender identities.
Queer	An umbrella term for anyone who identifies outside the norms of sexual or gender identity; an alternative term that resists the limitations of binary classifications.
Questioning	A term that describes a person who is in the process of exploring and discovering their sexual orientation, gender identity, and/or gender expression.

Source: Hillier, et al., 2010; PFLAG 2016b

experiences; and many who self-identify as gay or lesbian have not had sexual intercourse at all (Canadian Paediatric Society, 2008; Savin-Williams, 2005, 2006). These observations illustrate the complex process of forming a nontraditional sexual identity.

In the context of a strong heterosexual social norm in the family, community, and peer group, the idea of recognizing same-sex attractions and initiating same-sex sexual behaviors may not be enough to support a young person's decision to openly claim a minority sexual orientation. Even in the contemporary context of increasing awareness and acceptance of sexual diversity, many sexual minority youth perceive an atmosphere of rejection or hostility that inhibits their willingness to openly disclose an alternative sexual orientation (National Academies Press, 2011).

The development of a sexual identity for gay, lesbian, bisexual, and pan-sexual youth is an ongoing process which takes place in a social and historical context.

> Being pansexual is something I have always known to be true about myself. From a young age I was always aware that my attraction to people is not limited by their gender or sex, but I lacked the words to explain this. At 12 years old I was introduced to the term "bisexual" by a friend, who was attracted to both girls and boys. I finally felt as though I had a word for how I felt.
>
> As years passed, my knowledge expanded, and I discovered the many different gender identities on the spectrum. Pansexuality soon entered my vocabulary, and it has stayed with me ever since. (Kahn, 2015)

Four milestones of sexual identity development are relevant: awareness of sexual attractions; self-labeling as lesbian, gay, bisexual, pansexual, or queer; disclosure of one's sexual orientation; and sexual experiences (National Academies Press, 2011; Savin-Williams, 1996). Self-labeling and disclosure are discussed in more detail below.

Self-Labeling. Self-labeling, applying a label such as gay, lesbian, or bisexual to oneself, may begin with experiences in early childhood when boys or girls recall feeling different from their peers. These feelings, typically captured in retrospective studies of gay or lesbian young adults, may include a general sense that they did not share the same interests as others of their same sex. Boys may recall being more sensitive than their peers or being drawn to more artistic and aesthetic interests. Girls may remember passionate, mysterious friendships in the pre-pubertal and early adolescent period (Diamond, 2000). In many instances, these feelings of being different are associated with confusion and a sense of isolation or lack of belonging. Ronan recalls his early awareness, before he was able to label his interests:

> I guess I have pretty much always been a bit queer. I liked wearing all the women's clothes in dress ups at preschool and kindergarten. In role playing games I was always female. I don't know why. I was different: I didn't like sport, I liked to read and was good academically. I've never had many male friends; the ones that mattered were always female. I think I've been a bit effeminate. Not that all gay people are like that, but I was and always felt different. (Hillier et al., 2010)

Often, at puberty, the implications of these earlier childhood experiences become more evident. A growing awareness of one's own sexual interests and fantasies, coupled with new information about the variety of sexual orientations that may exist in the peer group or community, leads to new insights about one's own sexual preferences. In some ways, this may be a shocking realization. In other ways, it may help focus and clarify feelings of uncertainty and dissociation that had been difficult for the child to understand at an earlier age. Ronan describes the clarifying experience of being sexually attracted to a male friend.

> I had a few platonic crushes on girls and would go home and masturbate over other guys. I didn't think there was anything wrong with that until grade 8 when I had my first crush on a boy. He was one of my few male friends. I had seen him with his shirt off during swimming and was attracted immediately. I realized other guys didn't feel this way, and I was different even more so than I thought. (Hillier et al., 2010)

Not all young people who eventually recognize their same-sex sexual orientation reach the point of self-labeling in adolescence. With the greater visibility, openness, and acceptance of differences in sexual orientation and the presence of gay, lesbian, and bisexual role models, it is increasingly likely that this will happen. However, some young people resist the labeling process altogether: "I don't like to pigeonhole myself as one thing or another, so *queer* works well for me" (Hillier et al., 2010).

Disclosure. **Disclosure**, sharing information about one's sexual orientation with others, may be a prolonged process in which young people carefully decide which individuals can be trusted with this information, or it can be a very open, obvious statement of personal identity. Reports of adolescents who are openly gay suggest that disclosure can be very stressful when it is accompanied by negative reactions from parents and friends and by acts of open hostility from school peers (Burton, Marshal, Chisolm, Sucato, & Friedman, 2013). Sexual minority youth continue to experience sexual minority specific victimization, which is associated with fears about attending school, stress-related behaviors such as smoking and binge drinking, and higher rates of depressive symptoms and suicidal thoughts (CDC 2015e; Human Rights Campaign, 2014). Anticipating the strong social censure attached to an unconventional sexual orientation, adolescents may deny or mask it by functioning as heterosexuals during early adolescence.

> I feared not being liked and being alienated. I was president of various school clubs, and once I beat up a guy for being a faggot. I was adamant that fags should be booted out of the Boy Scouts. Other kids asked me why I was so rough on them. I did not say. No one suspected me because I did sports and had several girlfriends. (Savin-Williams, 1996, p. 169)

Disclosure typically occurs first with close friends, and later, if at all, with family members. Studies of gay, lesbian, and bisexual youth suggest that parental acceptance and the ability to maintain closeness and autonomy with parents after disclosure are very important to a young person's continued identity development and well-being (Ryan, 2009). Even when disclosure is accompanied by negative reactions, it has many emotional and social advantages. By disclosing, the young person has a greater sense of authenticity and freedom. Once adolescents disclose to their friends and family, they can be more readily integrated into the gay community and find others who will help support their emerging identity. They can direct more of their effort to the task of integrating their gender identity, sexual identity, and social relationships and figuring out how to cope with the challenges that their minority sexual orientation poses.

However, disclosure continues to be accompanied by risks in many communities. In a nationally representative sample of youth, those who self-identified as sexual minority youth were more isolated, had fewer social connections, and had lower social status in their peer network that youth who self-identified as heterosexual. For boys in particular, this degree of social isolation was a strong predictor of depression (Hatzenbuehler, McLaughlin, & Xuan, 2012). Despite growing societal awareness of the diversity of sexual orientations, sexual minority youth continue to face negative attitudes from teachers, peers, and community members; possible social rejection from family members; and difficulty finding age-appropriate, non-exploitive sexual partners. The formation of school-based support groups such as the Gay-Straight Alliance play an important role in creating a more inclusive, less threatening environment for adolescents who are questioning their sexual orientation (Heck, Flentje, & Cochran, 2011). PFLAG (Parents and Friends of Lesbians and Gays) is an advocacy group that provides education, information, and community services to support families and allies of LGBTQ youth. The Harvey Milk High School in New York was the first high school to purposefully focus on creating a safe, supportive environment for LGBTQ (lesbian, gay, bisexual, transgendered, and questioning) students. As the broader societal system becomes more open about diverse sexual orientations and practices, the process of identifying, labeling, and disclosing an alternative sexual orientation should

become less stressful. For ideas and inspiration about how to bring about positive change for LGBTQ youth, check out the "It Gets Better" project, a collection of over 50,000 videos where people and groups tell their stories.

Transgender Youth

Transgender refers to gender identity, not to sexual orientation. It includes anyone whose gender identity differs from the sex assigned at birth. A transgender person may be straight, gay, lesbian, or bisexual. Although it is difficult to know for certain how many people are transgender, one estimate is that 0.3 percent of the U.S. population believes that their biological sex does not correspond to their gender identity. Transgender children are insistent that they have been labeled as the wrong sex. They are not just resisting the socialization norms for what is expected of boys and girls; they strongly feel that they are in the wrong body. By puberty, the reality of being transgender becomes clarified. In a study that followed gender dysphoric children under the age of 12, 37 percent persisted in their commitment to a transgender identity by age 15 (Russo, 2016).

Problems and Conflicts Associated with Sexuality

The sexual system is one of the most problematic components of psychosocial development for young people in the United States. Five issues are taken up: lack of a consistent approach to sexual health education, reactions to first intercourse, sexual victimization, inconsistent contraceptive use, and exposure to sexually transmitted diseases.

Sources of Sexual Health Information. Where do teens get their information about sexual health? Formal sex-education that takes place in schools is a primary source. Yet, the percentage of schools that provide education on a range of topics has declined from 2000 to 2014 (see FIGURE 9.3 ▶). The majority of teens say they have received formal instruction about HIV, other sexually transmitted infections, and how to say no to sex. But far fewer have received formal instruction about birth control, where to obtain birth control, or how to use a condom. What is more, the information about pregnancy prevention, contraception, and how to use a condom is more likely to be taught at the high school level than the middle school level. Many students are already sexually active before they have this formal sex education. And 88 percent of schools allow parents to exclude their children from sex education (Guttmacher Institute 2016b).

Parents are another important source of information about sexual health. The majority of teen girls and boys say they have talked with their parents about at least one of the topics typically covered in a course on sexual health. However, many parents acknowledge that their information about contraception and other topics is incomplete. Pediatricians and primary care physicians can provide confidential consultation about sexuality, but relatively few teens feel comfortable talking with their doctor about their sexual health. And likewise, most health care professionals don't feel comfortable talking with teens about sexual health (Guttmacher Institute 2016b).

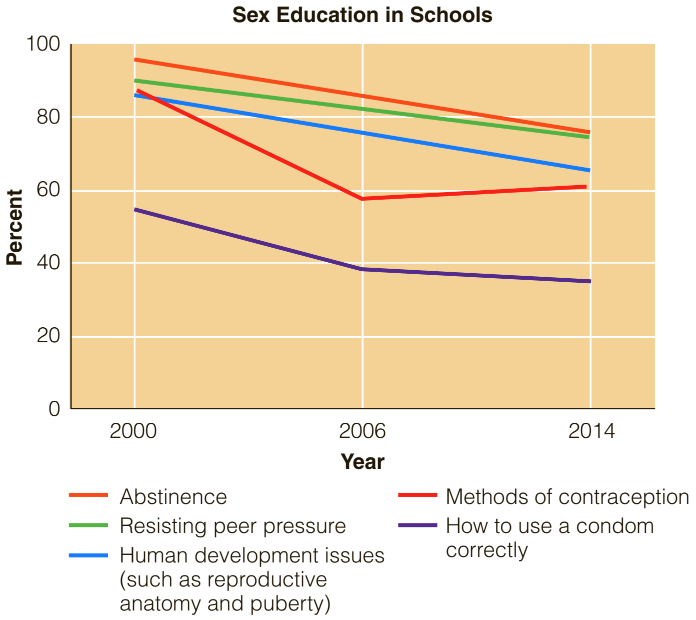

FIGURE 9.3 ▶ CONTENT OF SEXUAL HEALTH EDUCATION, 2000–2014

Source: Guttmacher Institute, (2016). American Teens' Sources of Sexual Health Education. Retrieved from the internet on May 29, 2016 at https://www.guttmacher.org/fact-sheet/facts-american-teens-sources-information-about-sex

Digital media provide another important source of information about sexual health. More than half of 7th through 12th graders say they have used the Internet to find information. Websites can offer medical information, information about sexual relationships, and interactive sites where teens can ask questions and get responses from experts as well as from other teens. The U.S. National Library of Medicine provides a website just for teens including links to information about sexuality and birth control. However, not all websites claiming to provide information about sexual health for teens are accurate or up-to-date (Guttmacher Institute 2016b).

Teens encounter information and approaches to sexual health that may be confusing or conflicting. For example, in the late 1990s, the U.S. Congress authorized funding to support programs that taught abstinence as the primary approach to sex education. These programs, referred to as Abstinence Only, were required to teach about the social, psychological, and health benefits of abstinence; the risks of sex outside of marriage; and the importance of monogamy. At the same time, national studies show that the vast majority of both men and women are not virgins when they marry. Adolescents realize that abstinence is not being practiced by most unmarried young adults, and was not practiced by their parents' generation when they were young. And imagine getting formal sex education that presents abstinence only when you are already sexually active.

Systematic evaluations of sex education programs find that comprehensive sex education based in a framework that emphasizes gender roles, empowerment, diversity, and human rights has a much greater impact on reducing unwanted pregnancy, improving contraceptive use, and reducing sexually transmitted diseases than abstinence only programs (United Nations Population Fund, 2015). Abstinence from sexual intercourse can be an effective strategy for reducing exposure to sexually transmitted diseases and is probably a good choice for teens in the early phases of pubertal development. However, it simply is not effective in preventing the undesired risks associated with early or unprotected sex.

The abstinence approach is ineffective in the United States. From 2004 to 2013, the United States spent $1.4 billion on an "abstinence and faithfulness" program in sub-Sahara African countries in an effort to reduce the risk of HIV transmission. Population studies found no differences in the high risk behaviors between countries that received the program and those that did not (Lo, Lowe, & Bendavid, 2016). Some experts claim that federally funded sex education programs that omit comprehensive, medically sound information about contraception, sexually transmitted diseases, unwanted pregnancy, and abortion are contradictory to public health goals and deprive youth of their human rights (Santelli et al., 2006).

Reactions to First Intercourse. What is the first experience of sexual intercourse like for teens? A national survey of over 4,500 teens ages 15 to 19 showed that slightly over one fourth had their first experience intercourse experience; by ages 18 to 19, two-thirds had experienced sexual intercourse. The majority said their first experience was with someone they were "going steady" with (70 percent for females; 56 percent for males), but another significant group (16 percent of females and 28 percent of males) said they had intercourse the first time with someone they just met (Martinez, Copen, & Abma, 2011).

When college students were asked to reflect back on their first experience, about one fourth expressed regret, which was more likely among women than among men. Women who were young, age 15 or under, are more likely than older teens to feel bad or used, often because the first experience was with an older male who was not really committed to the girl. Those who had a first sexual experience while under the influence of alcohol or drugs were also more likely to express regret (Reissing, Andruff, & Wentland, 2011). Moreover, more than twice as many men than women described their first experience as physically satisfying (65 percent of men versus 25 percent of women). Fewer women than men described their first experience as emotionally or psychologically satisfying (38 percent of women versus 57 percent of men). When the first experience took place within a committed or steady relationship, it was more likely to be described as psychologically satisfying (Higgins, Trussell, Moore, & Davidson, 2010).

Sexual Victimization. Adolescents' sexual experiences can occur in a variety of relationships from stable and serious to very intermittent and casual. Within these contexts, aggressive, abusive, and exploitive behaviors also take many shapes from the most serious forms of rape to unwanted touching to sexualized attention and teasing. A national survey of children's and teen's exposure to violence documented sexual victimization experiences in the following categories: sexual assault, statutory sex offense, peer flashing, dating violence, and Internet/cell phone harassment. Among 14 to 17 year olds, 27 percent reported experiencing sexual victimization in their lifetime. Among teens in this age group, 20.3 percent reported sexual Internet or cell phone harassment; 10.6 percent reported experiences of sexual assault; 8.3 percent experienced peer flashing; and 6.3 percent experienced dating violence, which can include physical aggression, stalking, emotional or psychological threats, or sexual coercion (Finkelhor, Turner, Shattuck, Hamby, & Kracke, 2015). These figures are likely underestimates given that many teens are unwilling to report or reveal their experiences.

Beyond the more violent forms of sexual victimization, many adolescents are exposed to **unwanted sexual attention**, including teasing, verbal insults, and gestures, which can be perceived as threatening, embarrassing, or harmful. The impact of this sexualized attention is difficult to determine; it may be viewed as playful teasing or flirting by some, but it may be viewed as offensive or harassing by others. In a study of potentially offensive sexual behavior (POSB), three types of behavior were considered: (1) physical and verbal behavior like sexual jokes, sexual touching or pinching, pulling on someone's clothes in a sexual way, or making comments about someone's body parts that make them a boy or a girl; (2) electronic behavior like showing, sending, or leaving someone sexualized messages or pictures, or sending someone sexualized messages or photos on websites; and (3) homophobic behaviors like calling someone *gay*, *fag*, *dyke*, *queer*, or something similar. Among ninth graders who were surveyed, 72 percent reported at least one of these types of behaviors toward cross-sex peers and 77 percent reported at least one of these types of behaviors toward same-sex peers. For boys, the most common form of POSB was "made sexual comments, jokes, gestures or looks about someone." For girls, the most common form of POSB was "called someone *gay*, *fag*, *dyke*, or *queer* or something similar." It is not surprising to find common patterns of use between teens and their friends. Teens who were more likely to engage in POSBs also had friends who reported frequent POSBs (Jewell, Brown, & Perry, 2015).

Electronic media play an insidious role in the current environment of sexual victimization (Wildsmith, Barry, Manlove, & Vaughn, 2013). Teens are taking and sending pictures of their bodies, including nude images or images of their genitals, on their smartphones. In some cases, these pictures are sent as a way to "show off" or get someone's attention. In other instances, the pictures are taken without the person's awareness or consent and circulated to the peer community. Even when the original image was intended just for a boyfriend or girlfriend, the images posted on Facebook or Instagram or through a text message can be shared with the larger community, resulting in a barrage of harassing, insulting, and humiliating comments. Most states have laws that make the circulation of explicit sexual images of minors illegal; it is considered child pornography. However, the victim of the "sexting" has no way of stopping the spread of these images to a wider network. The results of this form of unwanted sexual exposure can be devastating (Burleigh, 2013; Rosen, 2014).

The boundaries for acceptable sexual contact are unclear; the sexual agenda for boys and girls is likely to be very different; the perceived potential rewards for sexual experimentation are great; and other risk-taking behaviors, including alcohol and drug use, may create an environment for these unwanted or violent sexual encounters (Vagi et al., 2013).

The lack of supervision and monitoring by adults, as well as the lack of opportunity to talk about sexuality with them, can place adolescents at risk for early sexual experiences that are abusive or associated with negative feelings. The sex-linked problems that many people encounter—unintended pregnancy, marital infidelity, rape and other forms of unwanted sexual contact, child sexual abuse, pornography addiction, and sexually transmitted diseases—are evidence that the socialization process—including efforts by parents, teachers, and religious leaders—is failing to promote mature sexuality in significant numbers of adolescents and adults in the United States.

Inconsistent Contraception. Despite the decline in the inclusion of information about methods of contraception and the use of condoms in formal sex education, the use of contraceptives by U.S. teens has increased. In a survey conducted between 2011 and 2013, 79 percent of females and 84 percent of males used some form of contraception during their first sexual intercourse. Among females who were sexually active, 97 percent had used a condom as a method of contraception at least once. However, the next most commonly used method reported by females was withdrawal (60 percent) (Martinez & Abma, 2015).

Although contraceptive use has increased among adolescents, its use continues to be inconsistent. In part, this is because sexual activity among many adolescents is sporadic. Other explanations for inconsistent use include misunderstanding about pregnancy risks and the need for **contraception**; lack of skills in the use of contraceptives and a desire to avoid embarrassment; barriers to acquiring contraceptives including cost, lack of anonymity, and religious or cultural barriers; poor communication among the partners about who is responsible for contraceptive use; experiencing side-effects associated with various forms of contraception; lack of knowledge about the effectiveness of various types of contraception; a view that using contraceptives, especially the use of a condom, intrudes on the spontaneity of sexual activity; and the involvement of drugs and alcohol with sexual activity, which may increase impulsiveness and reduce reasoned decision making (Reed et al., 2014; U. S. Department of Health and Human Services, Centers for Disease Control and Prevention, 2006).

Many adolescents are confused about the difference between contraception for the prevention of pregnancy and contraception for the prevention of STIs. For example, girls might say that they were more likely to expect a boy to use a condom if this was a casual sexual relationship, but that it wasn't necessary if it was a steady relationship (Reed et al., 2014). As the quote below suggests, a young woman's intention to use contraceptives effectively may be at odds with her understanding about their various purposes.

> Jane answered unequivocally "yes" to the question whether young people she knew would use condoms every time they had sexual intercourse. But she added: "Depending on whether they didn't want to—and whether the girl's on the pill and they were in a steady relationship and they didn't want to use one. But otherwise most people would use them." (Kirkman et al., 1998)

One direction that is gaining increasing support in the public health community is offering teens the option of long-acting, reversible contraception (LARC), including an intrauterine device or an implant. These options avoid the need for frequent decision making, have proven to be highly effective in preventing pregnancy, and give young women greater protection against unwanted or unplanned pregnancies until they are ready to have a child (Northridge & Coupey, 2015). Evidence from a statewide initiative in Colorado that offered free long-active reversible contraceptives to teens resulted in a 40 percent decrease in teen pregnancies and an accompanying 42 percent reduction in abortions for this segment of the population over a 4 year period when the intervention was implemented (Tavernise, 2015). One concern with this direction is that the LARC does not prevent the spread of sexually transmitted infections.

In this classroom the teacher is showing students wrapped condoms as part of her instruction about safe sex. This is not always permitted as part of sex education, especially in programs that promote abstinence only.

Sexually Transmitted Infections. In 2014, the CDC reported increases in the number of the three sexually transmitted infections (STIs) that are tracked: chlamydia, gonorrhea, and syphilis. An estimated 20 million new cases of STIs are reported annually, roughly half to early and later adolescents aged 15 to 24. Adolescents aged 15 to 19 accounted for 20 percent of the new cases of gonorrhea and 26 percent of the new cases of chlamydia (CDC 2015e). Untreated, chlamydia and gonorrhea in young women can produce pelvic inflammatory disease, leading to infertility and abnormal pregnancies. In a study that tracked young women ages 14 to 17, within

1 year of their first sexual intercourse, 25 percent of the sample had their first sexually transmitted infection (Tu et al., 2009).

In 2014, 20 percent of the new HIV cases (9,731 cases) were among individuals in the age range 13 to 24. Most of these cases are a result of sexual transmission, the majority involving adolescent males who have sex with men or are bisexual (CDC 2015e). Although adolescents believe that they have a strong understanding of AIDS as a disease, including its transmission and prevention, often their knowledge is confused or incorrect (Meschke, Bartholomae, & Zentall, 2002). At the same time, adolescents express little interest in learning more about AIDS; 84 percent say that they have been taught about HIV/AIDS in school (Centers for Disease Control and Prevention, 2012d). However, HIV/AIDS instruction is not being covered soon enough, and the percentage of schools that include systematic HIV/AIDS prevention has declined from 64 percent in 2000 to just over 40 percent in 2014. Even when students have had classes on sexual health, many young people overestimate how well they understand this health problem. Others are cynical about getting the specific information they need from typical school-based sex education courses, especially when these courses teach abstinence as the most effective method to avoid pregnancy, HIV, and other STIs. These courses often fail to provide the practical information that is needed to resolve questions about contraception and other sexual health topics. For example, only 39 percent of health education courses taught the correct use of a condom in a required health education course, even in programs intended to focus on HIV/AIDS prevention (Centers for Disease Control and Prevention, 2012d).

Efforts at prevention are typically targeted to individuals. However, broader system factors need to be incorporated into efforts to reduce the risks of infection and disease among adolescents. A variety of factors specifically impacting teens includes ineffective sexual health education; peer norms; media influences; and the availability, privacy/confidentiality, and costs associated with health service resources (CDC 2015e).

Parenthood in Early Adolescence

One of the consequences of early entry into sexual activity and inconsistent use of contraception is **adolescent pregnancy**. In 2014, 249,078 infants were born to young women ages 15 to 19 in the United States. The birth rate was 10.9 births per 1,000 girls ages 15 to 17, and 43.8 per 1,000 girls ages 18 to 19. These rates are at an all-time low for the United States, with steady declines from 1991 to the present (Hamilton et al., 2015). Declines in teen pregnancy rates were observed for all race/ethnic groups.

In efforts to explain the decline in birthrates to young mothers, data were collected that focused on sexual activity and contraceptive use. Both delays in the initiation of sexual activity and more effective contraceptive use contributed to the decline in teen pregnancy. Despite the encouraging trends, health experts are concerned that 17 percent of births to teens 15 to 19 are repeat pregnancies (roughly 26 percent of the births to 19 year olds), a fact that places the young women at risk for negative health, educational, and social outcomes and also increases the chances that the infants will be born preterm and/or low birth weight (Martin et al., 2012; WebMD, 2014). What is more, even at this historic low level, the birth rate to teens in the United States is substantially higher than the rate in other developed nations.

Predictors of Teenage Pregnancy. Are there any characteristics of teenage girls or their family and community contexts that are systematically linked to the likelihood of becoming pregnant? Using two national samples, Mollborn and Morningstar (2009) compared teenage girls who were pregnant to similar age girls who did not become pregnant and to women who became pregnant at age 20 or older. The risk factors for becoming a teenage mother included low parental education, having low grades in school, being in a single-mother or stepparent family, and having had sexual intercourse. For those girls who lived in very low-resource households, being poor coupled with high levels of distress combined to predict the increased likelihood of teen pregnancy.

Consequences of Teenage Pregnancy. The phenomenon of teenage parenthood is complex, touching the lives of the adolescent mother and father, the child or children born to them, their parents, and the schools, counseling services, and family planning services that have been created to help young parents cope with parenthood. The consequences for the young mother and her infant depend on the psychosocial context of the pregnancy. Within the time period of early adolescence, there is a big difference between becoming a mother at 14 or at 18. For the younger teens (i.e., those younger than 14), the pregnancies are typically unplanned and often a result of involuntary or forced sexual encounters. Younger teens are more likely to end their pregnancy by abortion. For the older teens, the girl's partner is usually within 2 years of her age, and even if the pregnancy was unplanned, the majority of girls go ahead with the birth. Very few teen age girls decide to allow their babies to be placed for adoption.

The most significant measurable impact of early pregnancy is its association with subsequent poverty. Teens growing up in high-poverty neighborhoods are at greater risk for teenage pregnancy and dropping out of school, both of which contribute to continuing poverty in adulthood. By the time their children are 3 years old, 50 percent of women who had a child before the age of 20 were living in poverty (The National Campaign, 2012). This effect is mediated through other personal and family factors that unfold following the first birth, such as continuing in school, repeat pregnancies, the chances of getting married, the kind of work one does, one's personal earnings, and the earning capacity of other family members.

Complications during labor and delivery may be devastating to the newborn's health. Young mothers more likely than older ones to experience such complications. Mothers under 19 are less likely than older mothers to initiate prenatal care during the first trimester of pregnancy. Infants born to mothers under 17 are at greater risk than those born to women in their 20s and 30s. They have a higher risk of being born prematurely or with a low birth weight (WebMD, 2014). Thus, young parents are more likely to have to cope with the special needs of a child with developmental disabilities.

Complications of pregnancy and negative birth outcomes for adolescent mothers are linked to the contexts of pregnancy. One study found that in a sample of 170 African American teens, the pregnancy was unplanned or unwanted in about half the cases (Crosby, DiClemente, Wingood, Rose, & Lang, 2003). Other studies have linked sexual abuse in childhood with earlier sexual activity and teen pregnancy. Girls with a history of both poverty and reported child abuse are significantly more likely to be pregnant at least once by age 17 (Garwood et al., 2015). When pregnancy occurs in these abusive or exploitive contexts, it is often accompanied by alcohol or drug use, cigarette smoking, and heightened anxiety, all of which contribute to low birth weight and neurological impairments for the infants. Teens who become pregnant under these circumstances are more likely to be socially isolated and to become psychologically disengaged from their infants. In contrast, when pregnancy occurs in the context of family, peer, and partner support, teen mothers are likely to receive encouragement for their caregiving, greater financial support, and opportunities to engage in appropriate social and educational activities that contribute to their own psychosocial maturity (Bunting & McAuley, 2004; Salas-Wright, Vaughn, Ugalde, & Todic, 2015).

For some teens, the experience of motherhood has an enhancing or self-righting impact. In a comparison of adolescent mothers who ended their pregnancies through abortion and those who kept their babies, the latter group demonstrated some important changes in their behavior. Rates of delinquency declined in this group, and they reduced their cigarette smoking and marijuana use (Hope, Wilder, & Watt, 2003). Young mothers may be inspired by their infant to make a better future for themselves and their baby. This often means completing their education, creating a more stable home environment, and taking better care of their own health.

Adolescent Fathers. There is growing interest in factors that predict early fatherhood, as well as concerns about the impact of early fatherhood on subsequent development. Data from the National Longitudinal Study of Youth provided information about approximately 1,500 boys ages 13 or 14 who were studied over a period of 8 years. Participants reported their age at the birth of their first child. Overall, 140 participants or slightly over 9 percent became fathers before the age of 20. The following combination of individual, family, peer, and environmental factors predicted early age of fatherhood: boys who were involved in more delinquent behaviors and more substance use, boys who started dating at a younger age, boys whose mothers had less education and who had their sons while they were adolescents, boys who were living in a single-parent home or not living with their biological father, and boys who were living in more dangerous neighborhoods. After taking all these factors into account, sons of adolescent fathers were at greater risk for becoming fathers themselves in adolescence than were boys whose fathers were 20 or older at their birth. These findings suggest an intergenerational pattern of early fathering in which young boys learn about early sexual activity as a pathway into adulthood as part of the family socialization process (Sipsma, Biello, Cole-Lewis, & Kershaw, 2010).

Adolescent fathers are a diverse group. One estimate is that about 25 percent of teen boys who impregnate a teenage girl are antisocial; they view girls as sex objects who exist for their own pleasure and power. They are likely to deny responsibility for the pregnancy by claiming that birth control is a woman's job and refer to their own "uncontrollable sexual desire" as well as their fertility as evidence of their masculinity. These boys are also likely to be involved in other high risk behaviors including having multiple sex partners. They are the boys who support the negative stereotype about teen fathers as selfish, exploitive, and uncaring (Kiselica & Kiselica, 2014; Weber, 2012).

In contrast to this negative evaluation of teen fathers, three fourths of adolescent boys want to be recognized as involved and responsible fathers (Kiselica & Kiselica, 2014). These boys are likely to have been in what they describe as a committed relationship, many for a year or more, before the pregnancy. They have provided emotional and instrumental support to their partner during the pregnancy, and in many cases well through the infant's first year of life. Some adolescent fathers marry the mothers; others live with them for a while. Often, the couple continues to date. In some instances, they marry the child's mother several years after the child is born. In many cases, the father contributes financial support to the mother and child, even when the couple does not marry (Bunting & McAuley, 2004; Paschal, 2006). Being

EPF/Alamy Stock Photo

Not much is known about the impact of teen fathering on a boy's psychological development. What factors might influence whether the boy becomes committed to nurturing and supporting his child or leaves the parenting entirely to the mother and her family?

embedded in a strong social support system with the partner and the extended family helps to sustain the co-parenting relationship, providing essential stability for the child. The ability to establish a positive connection with his child also reinforces the teen's confidence in being able to continue on a path to responsible adulthood (Lewin et al., 2015; Mollborn & Jacobs, 2015).

Despite the desire to be a good provider and nurturer, adolescent fathers face a variety of challenges that may lead to a decline in support and reduced contact with their children. Many adolescent fathers have little education and are minimally employed, so the material support they can provide is limited. Conflicts with the child's mother and/or her family can result in being pushed away. Troubles with the justice system or the legal system, and difficulty finding or using needed services can be roadblocks to continued involvement with their child (Kiselica & Kiselica, 2014).

Little systematic research has been done on the attitudes, knowledge, or behaviors of adolescent fathers or the impact of fatherhood on a teenage boy's subsequent development. One study followed a large sample of adolescent boys through their teen years. Those who became fathers were characterized as having lower self-esteem and a lower sense of internal control than their age-mates who did not become fathers. Shortly after fatherhood, these boys experienced a boost in self-esteem, but in the next several years, their self-esteem declined to its pre-fatherhood level (Pirog-Good, 1995).

Any effort to provide services to teen fathers must begin with a nonstigmatizing approach. Successful programs typically recognize the diversity of needs facing teen fathers including job skills training, legal advice, educational opportunities, family life skills, and parenting education. Efforts to include young fathers in family planning programs, parent education, and employment training initiatives help strengthen the social context for the young mother and her child and contribute to the young father's psychosocial development (Kisela & Kisela, 2014).

For both girls and boys, a key to the prevention of early pregnancy requires building greater confidence in and commitment to the consistent use of contraception as part of any sexual relationship and comfortable, user-friendly access to reproductive health care. For girls, fostering a sense of self-efficacy and investment in academic goals leading to postsecondary education or professional training is an especially important area for intervention. For boys, building greater social expectations and commitment to assuming the financial and social responsibilities associated with fatherhood—including sending clearer messages from family and community that boys have responsibilities in these areas and devising specific opportunities for them to enact these responsibilities—seem promising directions for future intervention. For more information on pregnancy prevention programs, visit the website of the Centers for Disease Control and Prevention (CDC) and go to the Communitywide Teen Pregnancy Prevention Initiatives home page; also see the website of the National Campaign to Prevent Teen and Unplanned Pregnancy.

FURTHER REFLECTION: *Think about the impact of physical development, including the emergence of sexuality and sexual interests, on adaptation during early adolescence. Identify personal, family, cultural, and environmental factors that help adolescents cope effectively with these changes. What factors lead to dissatisfaction with body image, risk taking, and harmful or unhealthy behaviors? What factors may be contributing to the steady decline in teen pregnancies in the United States? Why does teen pregnancy continue to be a focus of public health and public policy initiatives?*

Formal Operations

OBJECTIVE 3 Identify the basic features of formal operational thought, and explain the factors that promote the development of advanced reasoning at this period of life.

Just as the body undergoes significant changes during puberty, so too does the brain and related mental activity. Early adolescents begin to think about themselves and their world in new ways that reflect a broadening of consciousness. This includes greater introspection or monitoring of thoughts, greater integration of information from various sources, and more focused planning and control of behaviors guided by goals and strategies. Young people are able to think about several dimensions at once rather than focusing on just one domain or issue at a time. They are able to generate hypotheses about events that they have never perceived and to use logical reasoning to evaluate evidence to support or disconfirm these hypotheses (Kuhn, 2009).

Brain Development in Adolescence

You will recall from chapter 4 that the brain is comprised of **gray matter**, the cell body of neurons and the non-myelinated sections of axons and dendrites, and **white matter**, the myelinated axons that connect gray matter and carry messages between nerve cells and brain regions. **Myelin** is a substance that forms around the axons, acting as an insulator that speeds signals from one neuron to the next. Gray matter volume and distribution are associated with competence in that region of the brain. White matter is associated with speed and efficiency of processing.

Brain development is ongoing throughout the prenatal period, infancy, childhood, adolescence, and adulthood. Like physical maturation, it is very individual, reflecting an ongoing interaction between genetics and environment. Brain development is characterized by periods of intense production of neurons and synapses followed by a process of sculpting and pruning when some connections are strengthened and others drop away. One of the most important discoveries related to adolescent brain development is that various areas of the cerebral cortex reach their peak in gray matter production during early adolescence, followed by a process of sculpting and pruning. The timing for these peak periods of gray matter production vary quite a bit from one person to the next, but the average is around ages 10 to 12 for the parietal lobe, ages 11 to 12 for the frontal lobe, and ages 16 to 17 for the temporal lobe (Lenroot & Giedd, 2006).

The process of sculpting and pruning that occurs during the course of the high school years strengthens certain neural networks while others fall into disuse. Whatever a young person does frequently will be woven into a strong, well-integrated network of neural signals. Through focused attention and repeated actions, a person can alter his or her brain architecture. Neural functions that are infrequently or rarely stimulated will weaken. Thus, the high school years provide a truly irreplaceable opportunity to shape a person's neural landscape, creating areas of unique competence and mastery that develop as a result of active engagement in certain thoughts and behaviors (Siegel, 2013).

In contrast to the production of gray matter, which shows an inverted U-shaped pattern, increasing from childhood through adolescence and declining in the late teens and early adulthood, there is a steady increase in the volume of white matter from ages 4 through the 20s. The prefrontal cortex, which is responsible for the full range of executive functions, is not fully developed until the late 20s.

Executive functions, sometimes called cognitive control functions, include:

Working memory. The memory system used for temporarily storing and managing the information required to carry out complex cognitive tasks such as learning, reasoning, and comprehension.

Planning and organizing. Devising an approach to a complex task, including following a sequence of steps to task completion and using feedback to revise one's plan.

Impulse control. Including resisting distractions, self-regulation, and behavioral inhibition.

The combination of changes in gray matter and white matter in the frontal, parietal, and temporal lobes and the resulting improvements in executive functions are associated with the following potential changes in mental competence during adolescence.

Ages 10.5 to 13: New growth in the visual and auditory regions of the brain; new ability to perform calculations; increasing ability to perceive new meanings and functions for familiar objects.

Ages 13 to 17: New growth in visuoauditory, visuospatial, and somatic systems; new ability to review mental operations (metacognition), especially the ability to find flaws in one's reasoning and to use information to revise problem-solving strategies.

Ages 17 to 30: New growth in prefrontal cortex: new abilities to question and evaluate information; new abilities to formulate hypotheses based on new information from a variety of sources.

The relationship of the brain and behaviors is bidirectional. Many studies have shown a relationship between maturation in the prefrontal cortex and improvements in executive functions including working memory and response inhibition (Giedd et al., 2012; Paus, 2005). At the same time, repeated activity, such as musical training, can alter brain structure. For example, a 3-month period of juggling practice was found to be related to an increase in gray-matter density in the motion-processing region of the brain (Draganski et al., 2004). In other words, the maturing brain makes new accomplishments possible for adolescents, and, at the same time, the effort and persistence an adolescent exerts toward advanced skill building stimulates new neural growth.

Piaget's Theory of Formal Operational Thought

Without the benefit of magnetic resonance imaging or other technologies, Jean Piaget proposed a qualitative shift in thinking during adolescence from concrete to **formal operational thought**. His theoretical formulation reflects what is now known as a dramatic advance in neural maturation that takes place during early and later adolescence (Inhelder & Piaget, 1958; Piaget, 1970, 1972a). In the period of concrete operational thought, children use mental operations to explain changes in tangible objects and events. Their approach to problem solving is concrete in that they rely heavily on observed features and direct experience to infer rules for solving problems. In the period of formal operational thought, young people use mental operations to manipulate and modify thoughts and other mental operations (Piaget, 1972b).

A central feature of formal operational reasoning is the ability to separate and distinguish between *reality* and *possibility*. Problem solving is altered as adolescents become better able to think about the bigger picture of choices and their likely consequences. As the brain matures, neural systems are linked together more quickly so that memories, concepts, language, sensory/perceptual capacities, and motor skills can be integrated for use in a faster, more efficient way. For example, in thinking about trying to get a part-time job, adolescents may consider the possibilities related to the kind of work they would like to do and the kind of work they think they are qualified to do. They may also consider realities such as the specific jobs that are available in their town, the number of hours they can work given other school and family commitments, the physical demands of the work, and their access to transportation. They are able to create different scenarios about working, based partly on what they want and partly on what they learn in the process of applying for jobs. Some of the possibilities they may have considered are no longer realistic, and some of the information suggests new possibilities that they may not have considered.

In the maturation of scientific reasoning, the ability to distinguish between reality and possibility results in the formal operational process of hypothesis testing. **Hypotheses** are tentative propositions or *possible* explanations about the causes of events or the systematic associations among factors that explain events. In the scientific process, one raises hypotheses to explain an event and then follows the chain of evidence to determine whether the evidence supports the hypothesis. One of the classic experiments that Piaget and Inhelder designed to demonstrate the development of hypothetical deductive reasoning involves the explanation of the swing of a pendulum. The task is to find out what variable or combination of variables controls the speed of the swing. Four factors can be varied: the mass of the object, the height from which the pendulum is pushed, the force with which it is pushed, and the length of the string. To investigate this problem, it is necessary to begin by isolating the separate factors and then varying only one factor at a time while keeping the others constant. As it happens, only the length of the string influences the speed of the pendulum. The challenge, then, is to demonstrate that the length of the string accounts for the speed of the pendulum and that the other factors do not. Children at the stage of concrete operational thought have difficulty coordinating the interaction among four separate variables and may lose track of what is being varied and what is held constant. After trying one or two strategies, they may simply give up. In contrast, being able to use formal operational thought, a child can create a matrix of variables and test each factor separately to evaluate its contribution (Flavell, 1963; Inhelder & Piaget, 1958).

Jim Cummins/Lithium/AGE Fotostock

The capacity for hypothesis testing makes it possible for students to evaluate the results of their experiments. How might you design chemistry experiments so that they are most likely to foster formal operational reasoning?

Six Characteristics of Formal Operational Thought

Formal operational thought is not a specific skill or expertise; rather, it is a way of approaching and solving problems based on new capacities for abstract, probabilistic thinking. Six conceptual skills emerge during the stage of formal operations that have implications for how adolescents approach interpersonal relationships, the formulation of personal plans and goals, and for how they analyze scientific and mathematical information (see Table 9.3). First, adolescents are able to mentally manipulate more than two categories of variables at the same time; for example, they can consider the relationship of speed, distance, and time in planning a trip. Second, they are able to think about things changing in the future. They can realize, for instance, that their current friendships may not remain the same in the years ahead.

Third, adolescents are able to hypothesize about a logical sequence of possible events. For example, they are able to predict college and occupational options that may be open to them depending on how well they do in certain academic coursework in high school. Fourth, they are able to anticipate the consequences of their actions. For instance, they realize that if they drop out of school, certain career possibilities will be closed to them.

Fifth, they have the capacity to detect the logical consistency or inconsistency of a set of statements. They can test the truth of a statement by finding evidence that supports or disproves it. They are troubled, for example, by the apparent contradiction between statements such as “all people are equal before the law” and the reality that people who have more money can afford better legal representation and are likely to have different experiences with the legal system than those who live in poverty.

Sixth, adolescents are able to think in a relativistic way about themselves, other individuals, and their world. They know that they are expected to act in a particular way because of the norms of their community and their culture. Adolescents also know that in other families, communities, and cultures, different norms may govern the same behavior. They realize that people are the products of societies with different sets of rules and norms.

These qualities of thought reflect what is *possible* for adolescents rather than what is typical. Most adolescents and adults approach problem solving in a practical, concrete way in their common, daily functioning. However, under the most supportive conditions, more abstract, systematic, and self- reflective qualities of thought can be observed and bring a new perspective to the way adolescents approach the analysis of information and the acquisition of knowledge (Lee, Anzures, & Freire, 2011). Science education is just such a context, where students may be encouraged to think hypothetically about the systematic interactions among multiple variables.

Table 9.3	**New Conceptual Skills That Emerge During the Stage of Formal Operational Thought**
1.	Ability to mentally manipulate more than two categories of variables simultaneously.
2.	Ability to think about the changes that come with time.
3.	Ability to hypothesize logical sequences of events.
4.	Ability to foresee consequences of actions.
5.	Ability to detect logical consistency or inconsistency in a set of statements.
6.	Ability to think in relativistic ways about self, others, and the world.

Factors That Promote Formal Operational Thought

Neurological development alone is not enough to foster formal operational thought. We have already addressed the importance of a healthy diet, getting enough sleep, and adequate physical exercise for optimal cognitive functioning. Healthy brain development must be coupled with a social environment that encourages hypothetical, abstract reasoning; opportunities to investigate and explore alternative solutions; and a symbolic capacity for carrying out mental representations and operations. The affective components of interest, motivation, and self-efficacy are also involved in sustaining engagement with complex problems and the emotional regulation that allows one to stay focused despite frustrations and failures.

Several environmental conditions facilitate the development of formal operational thought and reduce egocentrism. First, early adolescents function in a variety of role relationships that place both compatible and conflicting demands on them. Among these role relationships are son or daughter, worker, student, friend, dating partner, religious believer, and citizen. Early adolescents experience firsthand the pressures of multiple expectations for behavior. Conversations with parents provide a give and take where adolescents are expected to state their opinions, consider their parent's point of view, and reach a mutually acceptable decision. Participating in a variety of roles also facilitates relativistic thinking by demonstrating that what is acceptable and valued in one situation may not be in another.

Adolescents participate in a more heterogeneous peer group. When children move from their community elementary school to a more centralized junior high and high school, they are likely to meet other students whose family backgrounds and social class are different from their own. In studying and playing with these friends, they realize the extent to which their expectations for the future differ from those of their new acquaintances because their values are shaped by the families and neighborhood from which they come.

The use of formal operational skills can be observed in adolescent discussions of peer-related issues and in the formation of intimate or romantic relationships—domains that require a wide range of hypothesis raising and testing. An example of a conversation between a 15-year-old girl and her best friend follows.

> CINDY: I'm so frustrated I can't stand it. Before Sean and I started to date, he was nice to me. I enjoyed being with him. He said hello to me in the halls; we'd walk along together. We talked about all kinds of things. Now that we're going out, he seems rude and uncaring. When we're with other people, he jumps in when I start to talk, and his eyes say "be quiet." He breezes by me in the halls sometimes, and when we talk about things (if we talk), he acts as if he is always right. I don't think he cares about me anymore. What's going on?
>
> DONNA: I know he likes you because he tells me. Maybe you should talk to him and tell him what he does and how it makes you feel.
>
> CINDY: No, if I do that he'll get mad and he won't like me anymore. Why don't you talk to him?
>
> DONNA: No, that wouldn't do any good, because then he would know you talked to me about this and he would not like it, or he would just say what he thinks would make him look good.

As this conversation continues, many possible scenarios are proposed about why this behavior is occurring, and hypotheses are raised about what could be done. The girls propose likely outcomes of each set of possible actions and attempt to evaluate the results of each. Finally, a tentative conclusion is reached: Boys treat girls differently when they are involved in a boyfriend–girlfriend relationship than when they are not. In the just-friends situation, there is a tendency to treat the girl as an equal, but in the boyfriend–girlfriend situation, there is a tendency for the boy to expect that he should dominate the girl. A solution is derived: Cindy must shape up Sean. Because she still likes him and wants to go out with him, she must try to tell him how she feels and hope he will change his behavior so that it is supportive and comfortable for her.

The context of friendship between Cindy and Donna allows Cindy to trust discussing her problem with Donna so that they can examine it fully. It also allows Donna to disagree with Cindy without terminating the conversation. Thus, Cindy can get a somewhat different point of view on her situation and the two friends together can explore a personal problem on a more objective, rational basis than Cindy probably could have done on her own.

The third condition that fosters the development of the cognitive skills of early adolescence is the content

Robert Brenner/PhotoEdit

Conversations with parents often force adolescents to rethink their assumptions or come up with support for their decisions. Although this is not always pleasant, these kinds of interactions are an important stimulus for more advanced reasoning.

of the high school curriculum. Guided by Vygotsky's theory of a zone of proximal development, we assume that capacities for formal operational reasoning are ready to be nurtured and advanced through exposure to educational experiences that promote systematic logical reasoning and problem solving. Courses in science and mathematics formally introduce students to the logical relationships inherent in these disciplines and give them practice in a hypothetical deductive style of reasoning. Courses in the social sciences, such as child development, psychology, anthropology, or sociology, introduce students to the organization of societies, individual differences in perspective, and psychological mindedness. The fine arts and the humanities advance students' conceptions of ways the world has been or might be. They expand the repertoire of representational thought. According to Gardner's model of multiple intelligences (discussed in chapter 8), the visual arts provide a means of integrating and innovating spatial intelligence with interpersonal intelligence. Many high schools involve students in community service learning, an experience that helps promote a greater sense of connection to the community and appreciation for the diverse perspectives on community improvement. The more complex, differentiated academic environment of the high school can bring substantial gains in conceptual skills for those students who become actively engaged in its academic programs (Cohen & Sandy, 2007; Gehlbach, 2006; Yamauchi, Billig, Meyer, & Hofschire, 2006).

The following examples illustrate how high school course experiences contributed to students' formal operational reasoning.

> In my senior physics class we would learn new concepts then apply them by building something. For example we were learning about inertia so then we had to build a cart to hold a pumpkin and it had to go straight and travel a certain distance.
>
> An assignment that enhanced my logical reasoning and critical thinking was to design a school playground using specific software. I had to think about dimensions of my playground and logically think about safety issues in the design.
>
> In high school I took a money matters course that talked about saving money, stocks, loans, debt, and every other aspect of money. It made me think in a much more logical way because hearing it from someone other than my parents made it more real.
>
> In my AP art class my senior year my teacher gave us a topic and we had to do 20 pieces of artwork with that one topic/object. Mine was a seashell and water. It broadened my thinking to think of 20 different things to do with a seashell. (Newman, 2010)

Although schooling can be a vehicle that promotes formal operational reasoning, not all school experiences are equally effective in promoting abstract, hypothetical reasoning. In a review of over 1,500 literary assignments for students in six middle schools, only13 percent were characterized as encouraging higher level cognitive functioning, (The Education Trust, 2015). Keating (1990) described the following characteristics that are important in creating a cognitively stimulating school experience.

> Students need to be engaged with meaningful material; training of thinking skills must be embedded in a knowledge of subject matter, for acquisition of isolated content knowledge is likely to be unproductive; serious engagement with real problems has to occur in depth and over time; students need experiences that lead to placing a high value on critical thinking, to acquiring it as a disposition, not just as a skill; and many of these factors occur most readily, and perhaps exclusively, when students have the opportunity for real, ongoing discourse with teachers who have reasonably expert command of the material to be taught. (p. 77)

One does not expect to see a mature scientist or a profound philosopher by the end of early adolescence. A young person's formal operational reasoning awaits further encounters with a specific discipline and its full range of significant problems. However, the opportunity for cognitive growth during this period is extensive. Adolescents are able to generate novel solutions and apply them to current life challenges. They also are able to be increasingly objective about the problem-solving process and to gain insight into their own mental activity (Lee, Anzures, & Friere, 2011).

Criticisms of the Concept of Formal Operational Thought

In Piaget's theory, formal operational reasoning is viewed as the final stage in the development of logical thought. A number of scholars have pointed to limitations in this construction. Six criticisms are discussed here.

1. Although qualitative changes in problem solving are observed, cognition is much more variable than the strict stage approach might suggest. Adolescents solve problems in different ways depending on the domain, and adolescents as a group differ more from one another in their approach to cognitive problem solving than Piaget's stage concept might imply. Studies of brain functioning and information processing capacities suggest considerable diversity in the timing of emerging capacities and the ability to apply effective strategies (Giedd et al., 2010).
2. Some question whether there really is a qualitative, stage-like consolidation in the use of formal reasoning. Although most researchers agree that formal operational thinking exists and does characterize the nature of mature, scientific reasoning, many studies show that adolescents and adults typically do not function at the formal operational level and that their use of formal reasoning is inconsistent across problem areas (Bradmetz, 1999; Kuhn, 2009). For example, Neimark (1975) followed changes in the problem-solving strategies of adolescents over a 3 ½-year period. Even the oldest participants in her study, who were 15,

did not apply formal operational strategies across all problems. Research has not been able to confirm Piaget's claims that thinking becomes consistently more propositional across problem areas or that formal operational reasoning is a universal characteristic of adolescent reasoning in a variety of cultures. At the same time, the evidence does suggest that adolescents become more aware of the need to coordinate logic and evidence as they evaluate propositions (Keating, 2004). Even Piaget speculated that people were most likely to use formal operational reasoning in the area of their greatest expertise.

3. Formal operational reasoning is not broad enough to encompass the many dimensions along which cognitive functioning matures in adolescence. Information processing, another aspect of cognitive science, focuses on specific mechanisms for perceiving, encoding, and retrieving bytes or units of information. Increases in speed, efficiency, and capacity of information storage and retrieval have been documented during the period from ages 11 to 16 (Kwon & Lawson, 2000). These capacities can be applied to hypothetical reasoning but are not the same as formal operational thought. Improvements in logical reasoning may result in part from the ability to handle greater quantities of information more quickly and efficiently.
4. In addition to development in basic processing, there are gains in knowledge, both as a result of schooling and experience. Knowledge in each specialized subject, such as mathematics, language, or science, expands, bringing not only increases in logic but also increases in understanding the procedures or strategies that are most likely to work for a given problem. Complementing changes in specialized knowledge, adolescents demonstrate increases in self-monitoring and conscious control of mental activity, such as the ability to hold conclusions in abeyance while they examine alternative solutions or gather new information. These capacities for cognitive flexibility contribute to the potential for more mature solutions (Donald, 2001).
5. Some scholars claim that formal operational thought does not represent the apex or endpoint of adult thought and reasoning. As adults mature, they face many problems in which abstract, logical-mathematical reasoning must be integrated with the specific demands of the circumstances. This type of thinking is sometimes referred to as **postformal reasoning** because it emerges after the establishment of formal operational thinking. In adult life, problems may need to be reframed to suit the situation. The solution may need to be evaluated for its impact on many interrelated parties. The cognitive processes associated with psychotherapy, diplomacy, and leadership are all examples of what might be considered postformal reasoning (Richards & Commons, 1990; Torbert, 1994). Adolescents are just at the beginning of an expanding capacity to think about big, multidimensional scientific and social problems.
6. The emphasis in formal operational reasoning is on well-structured, logical problems with one correct answer. This misses the enormous array of messy, poorly defined, ambiguous social and emotionally laden problems that adolescents face. Decision making in daily life requires a person to think about several possible solutions, each one with potential costs as well as benefits. Think about the reasoning that Evelyn Cabrera may have used to try to convince her parents that it was acceptable to continue to be serious about her boyfriend, even when she was planning to go to college. Adolescent reasoning is likely to look less logical and systematic because many of the problems they are trying to address are embedded in complex cultural and social circumstances, and the "right answer" depends on one's point of view (Berg & Strough, 2011).

FURTHER REFLECTION: *Describe ways that schooling supports the development of formal operational reasoning. Judge how well the high school environment matches the cognitive developmental changes that take place during early adolescence. Identify two or three experiences from your own high school years that encouraged your abstract, multidimensional probabilistic or hypothetical thinking.*

Think back to the case of Evelyn at the opening of the chapter. How might she be making use of her formal operational reasoning to develop her plans for the future? How do these qualities of thought help Evelyn confront her parents' objections to her relationship with her boyfriend?

Emotional Development

OBJECTIVE 4 Examine patterns of emotional development in early adolescence, characterize the neurological processes associated with emotional expression, and describe the nature of three problem areas: eating disorders, depression, and delinquency.

Descriptions of adolescence often refer to new levels of emotional variability, moodiness, and emotional outbursts. However, this is also a time of increased emotional complexity, with new capacities to identify, understand, and express a wider range of emotions (Kang & Shaver, 2004). These capacities illustrate the interdependence of cognition and emotion, including interpreting and evaluating emotional signals, and reasoning about the consequences of expressing emotions, which may result in the control or management of emotional expression (Hoeksma, Oosterlaan, & Schipper, 2004). A major task during this time is to gain insight into one's emotionality and to expand one's capacity for empathy with the emotional state of others. This means accepting one's feelings and not interpreting them as a sign of going crazy or being strange. Adolescents who are highly sensitive to social expectations or overly controlled about expressing or accepting their feelings may experience a sense of shame about their emotional states. Attempts to rigidly control or defend oneself against feelings are likely to result in social alienation or maladaptive behaviors. In contrast, those who experience a diverse and well-differentiated range of emotions are also more likely to be characterized by greater openness to experience, empathy, and interpersonal adaptability (Kang & Shaver, 2004).

In the following sections, we review the neuroscience of emotion and cognition, pointing to the overlapping network of neural systems that operate as emotions are aroused, recognized, interpreted, and expressed or controlled; the diversity and complexity of adolescents' emotional life; and specific examples of internalizing and externalizing problems that result from difficulties in the management and expression of emotions.

The Neuroscience of Emotion and Cognition

A key feature of the human's adaptive capacity is the ability to detect and respond quickly to situations that threaten our survival. Some areas of the brain, especially the limbic system, detect threats, react intuitively to information, and produce quick emotional reactions to situations. The **limbic system**, which includes the hypothalamus, the hippocampus, the amygdala, and several other nearby areas, produces signals that identify the immediate situation as threatening, or link the immediate situation to other previously experienced dangers. The sound of an explosion, being hit or threatened with violence, or the experience of being caught in a raging storm are all examples of situations that could trigger an immediate threat reaction in the limbic system. When the system is activated, signals are sent to the adrenal gland, which releases stress-related hormones, especially adrenaline and cortisol, which prepare the body to deal with the threat. Adrenaline boosts energy supplies and increases heart rate. Cortisol adds sugars to the blood, providing a burst of energy, improves memory, and lowers sensitivity to pain. These reactions are referred to as *bottom-up processing*. In other words, the reactions are quick and relatively automatic, taking place without much conscious control.

Other areas of the brain, especially the prefrontal cortex, are more analytic. Information is evaluated, decisions are made, and a logical plan is formulated. The prefrontal cortex receives information from the limbic system, evaluates this information in light of the context, and makes an assessment of possible consequences of action. Information is then transmitted back to the limbic system to modify emotional signals and to the sensory-motor cortex to guide subsequent behavior. The frontal cortex control is referred to as *top-down processing*, a cooler, slower cognitive process that helps to regulate and manage the initial emotional reactions. The coordination of the limbic system and the prefrontal cortex is referred to as vertical control (Greenberg, Riggs, & Blair, 2007).

The **vertical control system** undergoes a process of maturation that is usually not complete until the 20s. In comparison to adults, adolescents are more emotionally reactive to negative stimuli, most likely because of the immaturity of the prefrontal control system (Cohen et al., 2016; Yuan et al., 2015). As a result, they are more likely to react rather than to withdraw from negative social cues.

Adolescents are also especially sensitive to rewards (Galván, 2013; Paus, 2009). The reward circuitry of the brain is responsible for producing dopamine, a neurotransmitter that is released during pleasurable experiences and that encourages actions toward anticipated rewarding or pleasurable experiences. This circuitry is more active among adolescents than among children or adults when they are experiencing primary rewards like a sweet tasting liquid, secondary rewards like money or prizes, or social rewards like recognition or praise (Telzer, 2016).

While we tend to think of rewards in terms of food, money, tokens, and other material reinforcements, social cues can also serve as rewards. Research in the field of social cognitive neuroscience provides evidence that adolescents are increasingly attuned to interpersonal and social cues such as facial expressions, hand gestures, and body movement that convey approval or disapproval. The adolescent's emotional reactions are especially intense as the brain processes information relevant to social evaluation (Somerville, 2013). The adaptive value of reading social cues, especially for detecting threat and for assessing potential friendship and romantic relationships, makes the increased sensitivity to complex social expressions all the more relevant to the developmental progress of social competence in early adolescence (Garcia & Scherf, 2015).

The increased sensitivity of the reward circuitry in adolescence has been implicated in a variety of maladaptive behaviors. The assumption is that the intense responsiveness to risky activities including rule breaking, drug and alcohol abuse, fast driving, and peer-instigated antisocial behaviors are reinforced by the over-production of dopamine in these contexts, which "overpowers" the executive functions of the prefrontal cortex. However, one can also find evidence for the adaptive functions of this system. It makes sense to think that from an evolutionary perspective, the reward centers of the brain would direct behavior toward activities that have long-term fitness implications. Some possibilities include the positive associations of dopamine production with creative expression, curiosity and exploration, achieving valued goals, performing socially valued actions, participating in meaningful ways to family well-being, or excelling in valued domains like leadership, academics, athletics, or the performing arts. Whereas some teens may find risky behaviors or ruthless behaviors to be accompanied by the "dopamine rush" others find this same surge of reward-related glow from contributing in meaningful ways to the well-being of their families, friends, or communities (Telzer, 2016).

Given the state of their brain development, one challenge that adolescents face is how to use their maturing executive functions under conditions of intense emotional arousal in order to avoid unnecessary risk taking. The prefrontal cortex is the site of a variety of executive functions, some of which help to manage strong emotions through monitoring one's internal state, interpreting the emotions, and finding acceptable ways for expressing or, if needed, inhibiting the expression of emotions. Other executive functions are useful for planning a course of action, evaluating possible consequences, and adapting to changing circumstances as the situation requires. As illustrated in FIGURE 9.4 ▶, the combination of

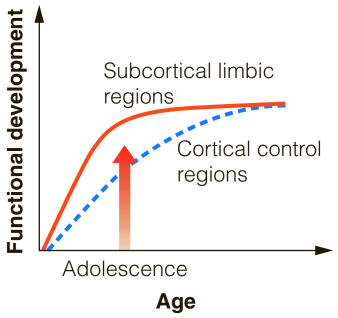

FIGURE 9.4 ▶ IMBALANCE MODEL OF NEUROBIOLOGICAL DEVELOPMENT

Source: Adpated from A. Galván (2013). The teenage brain: Sensitivity to rewards. Current Directions in Psychological Science, 22, 88–93.

these aspects of brain development may result in adolescents' need for greater stimulus seeking and the willingness for more risk taking. With a less fully developed prefrontal cortex, adolescents may have difficulty suppressing the immediate emotional responses of the limbic system. At the same time, they may engage in more intensely stimulating activities, some of which adults would judge to be highly risky, in order to achieve the desired experience of pleasure or arousal (Galván, 2012; Qu, Galvan, Fuligni, Lieberman, & Telzer, 2015).

Adolescents and adults are nearly equally able to understand information about the negative consequences of risky behavior. Early adolescents they may even overestimate the likelihood of their exposure to risk since they have relatively little life experience upon which to base their assessment of risks. However, if they engage in these behaviors frequently with no negative outcome, they are likely to conclude that the consequences are not as likely as they were led to believe. In gauging the risks and rewards of a decision, adolescents are likely to give greater weight to the rewards than to the possible negative consequences. Especially if the action is novel or one that provides social approval, its reward value can be quite high. What is more, the risks and rewards of certain behaviors are not the same for adolescents as they might be for adults. For example, the risk of being bullied, socially isolated, or embarrassed might be more serious for adolescents than for an adult. Imagine that Ken has to choose between calling his parents for a ride home from a party or getting a ride home from a friend who is intoxicated. While Ken's parents may view the risk of riding with an intoxicated friend as a great risk, Ken may view the risk of being seen by peers as overly dependent upon his parents as the greater risk.

In contrast to the vertical control system, through which the frontal cortex exerts control over the limbic system, there is also a horizontal control system that plays a role in risk taking and responses to threat. This **horizontal control system** refers to the flow of information between the right and left hemispheres of the brain. For right-handed children, the left hemisphere of the brain is the primary area involved in understanding spoken language, speech production, and the expression of positive emotions. The right hemisphere is involved in recognizing nonverbal expressions, processing positive and negative emotions, and expressing uncomfortable or negative emotions. The effective flow of information between the two hemispheres provides teens with the ability to use verbal skills to identify and regulate their emotional states. With maturity, adolescents are increasingly able to use language to gain greater control over their behavior and to explain their internal states to themselves and to others. Although executive control and verbal behavior are two separate cognitive capacities, they can work together to manage strong emotional states as well as to guide effective action.

The Diversity of Emotions in Adolescence

Adolescents are more aware than younger children of distinctions in their emotional states and are able to attribute them to a wider range of causes. Given an increase in awareness of social cues and heightened motivation for peer approval, adolescents may experience new levels of intensity in moral or social emotions such as guilt, shame, embarrassment, and jealousy as well as strong feelings of sympathy and loyalty toward friends and family (Malti, 2013).

In a longitudinal study using internet responses, close to 400 adolescents were asked to rate their daily emotions for five consecutive days three times a year over 5 years from ages 13 to 18. Each teen provided ratings of four types of emotions: happiness, anger, sadness, and anxiety. As illustrated in FIGURES 9.5a and b ▶, over the period of early adolescence, happiness declined and anxiety increased for the total sample. At age 13, boys and girls were about equally happy, but by age 18 the girls' happiness had declined more steeply than the boys. As for worry, the girls started out more worried at age 13 and continued to be more worried than boys by age 18 (Maciejewski, van Lier, Branje, Meeus, & Koot, 2016).

Emotional development in adolescence goes beyond the experience of new gradations of emotion and fluctuations in emotional intensity. With increasing executive control, adolescents acquire new abilities to monitor and manage their emotions. They can observe the rise in their own emotional intensity and recognize when this intensity is adaptive or disruptive. For example, in a competitive sports context, in preparation for a class presentation, or when inviting someone to go to a party, an adolescent can learn to use intense emotions to increase motivation

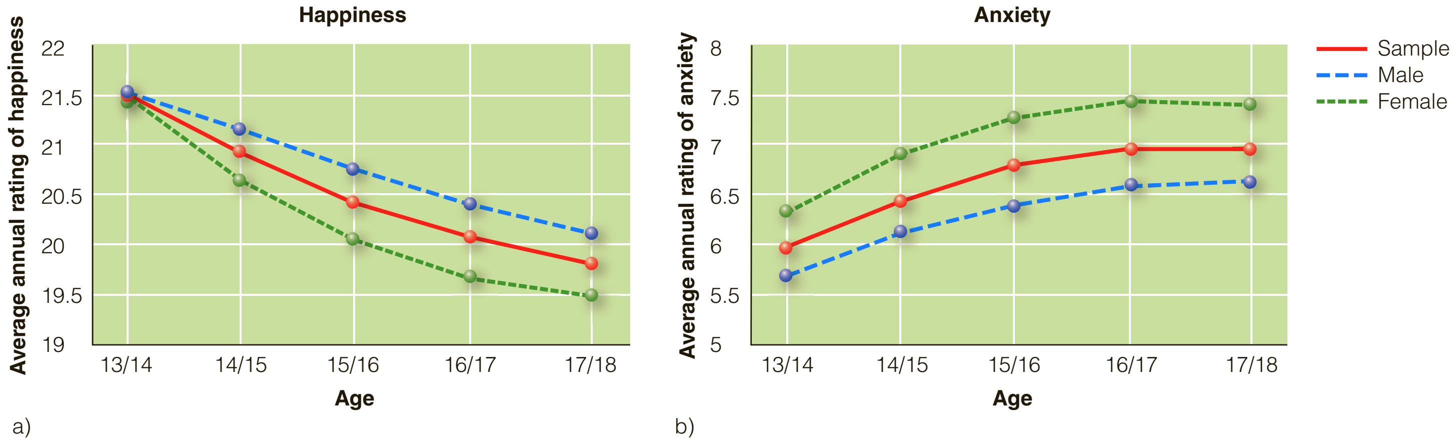

FIGURE 9.5 A AND B ▶ DEVELOPMENTAL TRAJECTORIES OF HAPPINESS AND ANXIETY FROM AGES 13–18.

Sporting events provide settings where adolescents can express their exuberant and wild emotions, including joy, pride, and anger.

and focus. Certain contexts like sporting events and pep rallies give adolescents an opportunity to experience the intensity of these intense emotions.

An adolescent can also learn self-calming strategies to reduce emotional intensity if it is distracting or disruptive. Adolescents' lives are strewn with episodes of pleasurable and distressing emotions, and teens become increasingly able to see how these emotional reactions might alter or distort their perceptions and judgments (Larson & Brown, 2007).

Internalizing and Externalizing Problems

After puberty, boys and girls show noticeably different levels of aggression and depression, with girls showing more problems coping with depression and boys showing more problems managing and controlling their aggressive impulses (Farrington, 2009; Graber & Sontag, 2009). These differences are often expressed in terms of **internalizing problems**, in which feelings of hopelessness or worthlessness are directed inward on the self, and **externalizing problems**, sometimes referred to as conduct problems, such as aggression or delinquency, in which the adolescent's conflicts are directed outward toward property or other people (Achenbach, 1991; Graber & Sontag, 2009). Three topics are discussed next: eating disorders, depression, and delinquency.

Eating Disorders.

Eating disorders are examples of internalizing problems—turning one's frustration, anger, anxiety, or fear inward on the self. Eating disorders are typically diagnosed in adolescence, and primarily but not exclusively among girls. Of the different types of disordered eating patterns that have been described in the medical literature, we focus on anorexia nervosa and bulimia nervosa. Each one can be expressed in more or less severe symptoms (NIMH, 2014).

Anorexia nervosa is characterized by a fear of gaining weight, extreme food restrictions, refusal to maintain a minimally normal body weight, and perceptions of one's body as overweight in general or in specific areas. Weight loss is viewed as an important accomplishment accompanied by increased self-esteem. Anorexia is observed about 2 ½ times more frequently in girls than boys, with symptoms most commonly observed after the onset of puberty. Adolescents with this condition focus their behavior on weight loss. They take an obsessive, determined position in rejecting most foods, accompanied by dieting, fasting, or excessive exercise. They also tend to have a distorted perception of their body image, seeing themselves as much fatter than they really are. With treatment, some patients recover, some have periods of recovery with relapses, and others experience an ongoing battle with significant declines in health. Unfortunately, only about one third of those struggling with anorexia seek treatment (Eating Disorder Hope, 2016). Without effective treatment, anorexia nervosa can cause the deterioration of many physical functions including bone loss, damage to the heart, and organ failure. According to the National Institute of Mental Health, anorexia is associated with the highest mortality risk of any psychiatric disorder (NIMH, 2014).

Bulimia nervosa involves recurring spurts of binging and overeating, followed by the use of different strategies to prevent the absorption of food, such as induced vomiting, the use of laxatives, or strenuous exercise. People with bulimia are usually able to maintain their body weight, but tend to experience body shape and weight dissatisfaction. Bulimia is more common in female adolescents but is experienced somewhat more commonly by male adolescents than is anorexia. Individuals who suffer from bulimia are usually ashamed of their eating and often eat in secret. Their eating is often experienced as a frenzy or an intense loss of control, followed by self-criticism and depression. Health risks associated with bulimia are linked to induced vomiting and laxative abuse including acid reflux disorder, inflamed and sore throat, severe dehydration, and intestinal irritation (NIMH, 2014).

The origins of eating disorders are not fully understood. A preoccupation with body appearance may be provoked by the relatively rapid physical changes associated with puberty. Many authors implicate the cultural infatuation with thinness as a stimulus of this condition. Support for this view comes from evidence that anorexia nervosa and bulimia nervosa are almost nonexistent in nonindustrialized countries where there are often food shortages and where thinness is not a cultural ideal. A combination of parent, peer, and media idealization of thinness, coupled with a tendency for girls to experience body dissatisfaction during puberty, leads teens to restrict their food intake and engage in faddish diets (Dunkley, Wertheim, & Paxton, 2001; McCabe & Ricciardelli, 2001; Stice & Shaw, 2004). In a national Youth Risk Behavior Survey, 31 percent of teens described themselves as slightly to very overweight, suggesting that they may be vulnerable to engaging in risky eating or dieting practices (Kann et al., 2014).

> Evie tells me that she learned how to throw up in school, in fact in health class, from a one-day lesson designed to discourage eating disorders. . . . Evie says she vomited after dinner three to five times a week off and on for almost a year. She didn't do it over the summer, she says, just when school was in session; and never during lunch—only after dinner, especially when her mother's boyfriend, a frequent guest at the table, urged her on to extra helpings of Tater Tots or dessert. On those nights,

> she'd wait until the dishes were done, then, a little while later, she'd mosey into the kitchen and pilfer a spoon. (Orenstein, 2000, p. 91)

The psychoanalytic view is that eating disorders link back to fear of sexual maturity and are an unconscious strategy to delay entry into adulthood. The family system perspective emphasizes the parents' control or over-control of their child's actions and preferences. Eating disorders, in this view, are a way for a child to exert control or power over one key area, eating, in a context where little power is permitted. In addition to these theories, some clinicians describe the adolescents who suffer from anorexia as having difficulty accepting and expressing their emotions. Compared with adolescents who have other types of emotional disorders, adolescents with anorexia show less emotional expressivity, greater timidity, and more submissiveness. Adolescents with anorexia have been described as "duty bound, rigidly disciplined, and moralistic with underlying doubts and anxious hesitancy" (Strober, 1981, pp. 289–290).

Certain genetic factors are associated with eating disorders. Twin studies provide evidence of a hereditary component to eating disorders. Three groups of genes are associated with eating disorders, especially through their role in emotional regulation, anxiety, and appetite suppression and weight gain or loss. The first group of genes influences the receptors and transporters of serotonin, which functions in the brain to control appetite, mood, sleep, memory, and learning. The second group of genes is related to brain-derived neurotrophic factor (BDNF), a protein that supports the growth of neurons in the brain. BDNF is also associated with appetite and weight gain or loss. Finally, genes associated with estrogen receptors have been tied to food intake as well as to depression and anxiety (Klump & Culbert, 2007). The exact role of each gene group in contributing to eating disorders or the severity of symptoms is not known. One hypothesis is that a few genes make the person vulnerable to eating disorders when they are exposed to certain environmental conditions. For example, girls who are engaged in specific types of activities such as ballet, gymnastics, or modeling, where weight is very important and where they are likely to be exposed to the stresses of competition and control, may be especially likely to develop eating disorders if they also have the genetic vulnerability that supports this condition.

Because of the seriousness and widespread nature of eating disorders, public health experts are working to create a more positive acceptance of people of various body types and shapes, with less focus on thinness. Advertisers are being urged to regulate ads promoting weight loss programs and products to children and adolescents and to disclose more accurately the amount of weight that can be lost. With the recent public health concerns about obesity, physicians may rely too heavily on height-weight tables as they discuss health with adolescents especially since those tables do not reflect individual variability in pubertal development at each chronological age. The current preoccupation with obesity may, in fact, contribute to a medically encouraged focus on thinness. The Academy for Eating Disorders has tried to encourage the fashion industry to support the health of models by setting minimal body mass index (BMI) guidelines for models. They oppose the trend of presenting design collections on extremely thin models. However, the United States does not regulate the fashion industry. In comparison to laws passed in France and Israel, there are no requirements for fashion models to have a medical exam to certify that they are of a healthy weight for their height and body type (Anvar, 2016).

Depression. There is growing concern about the number of adolescents who experience **depression**. According to a national survey, 30 percent of teens in grades 9–12 felt sad or hopeless almost every day for two or more weeks in a row during the past 12 months, such that they had to stop doing some of their usual activities (Kann et al., 2014). Depression can be observed in different patterns. The most likely pattern observed in adolescence is depressed mood; however, major depressive disorder is estimated to be observed in 4 to 5 percent of adolescents worldwide (Petersen et al., 1993; Thapar, Collishaw, Pine, & Thepar, 2012).

Depressed mood refers to feeling sad or despondent, a loss of hope, a sense of being overwhelmed by the demands of the world, and general unhappiness. Almost everyone experiences this kind of depression at some time or another, describing it as the blues, feeling down in the dumps, or feeling low. Related symptoms include worrying, moodiness, crying, loss of appetite, difficulty sleeping, tiredness, loss of interest in or enjoyment of activities, and difficulty concentrating. These bouts of depression may range from mild, short-lived periods of being sad and discouraged to severe feelings of guilt and worthlessness. A depressed mood may be predictive of more serious emotional disorders, but it is not in itself a clinical diagnosis. Depression appears to increase for both boys and girls during adolescence, with a peak at about ages 17 or 18 (Petersen et al., 1993). For many girls, a few days each month of depressed mood are associated with their menstrual cycle.

For a diagnosis of *major depressive disorder*, the adolescent must have experienced at least 2 weeks of a depressed mood or loss of interest or irritability, and four or more of the following additional symptoms in that same 2-week period: weight loss or weight gain, insomnia or sleep problems, restlessness or having difficulty moving, fatigue or loss of energy, feelings of worthlessness or inappropriate guilt, difficulties concentrating, and recurring thoughts of death, suicide, or plans to commit suicide (Graber & Sontag, 2009; NIMH, 2016).

Factors Associated with Adolescent Depression. No single known cause is accepted as the explanation for depression. Neuroimaging of the brains of individuals with major depressive disorder has identified an area of the prefrontal cortex that is reduced in size and shows reduced functional links with the amygdala, a region of the brain that is associated with the regulation of emotions. This observation of a disruption in the link between a higher order system that evaluates information, and a lower order system that recognizes and reacts to threat coincides well with the symptoms of major depressive disorder that combine cognitive deficits and difficulties in emotion regulation (Insel, 2007).

Recalling the research on the interaction between depressed mothers and their infants discussed in chapter 5 (Infancy), it is hard to separate genetic and environmental factors in the etiology of clinical depression. Having a depressed mother increases the risk of depression during adolescence. Teens whose mothers are depressed are characterized by more anxious attachments, more suicidal thoughts, and more frequent episodes of depression than teens whose mothers are not depressed (Essau, 2004). The direction of influence between brain and behavior is difficult to establish. Are some children more vulnerable to the negative impact of disrupted parenting because of some genetic neurological abnormality, or does the disrupted parenting produce a change in emotional regulation that eventually results in structural and functional abnormalities in the brain? These questions have not been fully answered.

Parental loss or rejection increases an adolescent's vulnerability to depression. In one longitudinal study of the consequences of economic pressures on families, a connection was shown between the family's economic stresses and increased parental depression. Economic strain is associated with heightened marital conflict, increased hostility, and less nurturance toward the children, resulting in subsequent adjustment problems in adolescent daughters, especially problems with hostility and depression (Conger et al., 1993; Tomarken, Dichter, Garber, & Simien, 2004).

Psychosocial adversity is associated with increased risks for depression. Adolescents are often exposed to more negative events than are younger children. Adolescents are more aware of what other people are experiencing, and because more is expected of them, there is more to worry about. School is more demanding, and there are more instances of high-stakes testing; selection or rejection in teams, clubs, and activities; and new performance standards (Locker & Cropley, 2004). Teens have a wider circle of relationships than younger children through which they are exposed to more problems, expectations, and disappointments.

Adolescents report experiencing hassles in the following domains: social alienation (disagreements with teachers, disliking other students), excessive demands (not enough time to meet responsibilities, not enough time for sleep), romantic concerns (dissatisfaction in a romantic relationship), decisions about one's personal future (important decisions about a future career), loneliness and unpopularity (being ignored), assorted annoyances and concerns (money problems, disagreement with a boyfriend or girlfriend), social mistreatment (being taken advantage of, having one's trust betrayed), and academic challenge (struggling to meet other people's standards of performance at school) (Kohn & Milrose, 1993). In this list, peer relations, including romantic relations and the elements of interpersonal experience that are part of being a member of a friendship group, play a central role.

Depression is linked to experiencing negative peer comparisons in areas that are considered to be important to others, such as good looks, athletic ability, having money, or having good social skills (Thwaites & Dagnan, 2004). Problems with peer relations can be a source of stress that triggers depression. At the same time, depression can lead to disruptions in peer relationships. Adolescents who are depressed may make more negative meaning of social interactions, feel more dependent on others to confirm their sense of self-worth, and have less energy or emotional resources for coping with experiences of rejection. Whereas having close friends who are not depressed may be a protective factor against depression, having friends who are depressed may actually induce a depressed mood. Depressed teens may ruminate about their problems, focus largely on negative experiences, experience more conflicts with each other, and generally convey dissatisfaction in their relationships (Brendgen, Lamarche, Wanner, & Vitaro, 2010). There is some evidence that girls who are depressed at age 15 are more likely to enter long-term romantic relationships with partners who are coercive, nonsupportive, and physically violent (Hammen, 2009). The implication is that depression plays a role in continuing to be exposed to stressful interpersonal relationships, which, in turn, create new sources of depression.

Adolescents are relatively inexperienced in coping with these kinds of stressors. They may not have developed strategies for interrupting or reducing the feelings of grief or discouragement that accompany stressful life events. The combination of pressures on parents, especially marital conflicts and economic pressures that affect youth, plus exposure to their own failures, disappointments, and loss of relationships with peers and in school, are clearly linked to a negative mood in adolescents, especially sadness and depression. Feelings of depression may be intensified by accompanying hormonal changes (Hartlage, Brandenburg, & Kravitz, 2004). Young people may become convinced of their worthlessness, and this distortion of thought may lead them toward social withdrawal or self-destructive actions.

Gender Differences in Depression. Most studies find no differences in depression between prepubescent boys and girls; however, during the period from about age 11 to 15, gender differences are systematically noted and continue to be evident into adulthood. Experiences of depression appear to be more common in adolescent girls than in boys (Graber & Sontag, 2009).

Several ideas have been offered to explain this gender difference. First, the estrogen cycle has been linked to changes in mood, with periods of low estrogen production linked to negative feelings and low self-esteem. One related hypothesis is that the estrogen cycle in girls is accompanied by a new sensitivity to stress, which results in new and more intense feelings of sadness, anxiety, and depression (Soares & Zitek, 2008). Second, at puberty, girls become critical of their bodies, especially concerns about being overweight and unattractive. This attitude may lead to prolonged feelings of dissatisfaction with the self and a consequent depression. When coupled with restricted dietary intake, girls may feel listless and drained of energy. Third, girls tend to look within for explanations of their failures and problems, blaming them on their own lack of ability; in contrast, boys tend to focus on factors outside the self, blaming other people or unfair conditions for their failures.

Fourth, even when girls receive strong social support from their parents and friends, they are also somewhat more sensitive to the problems that people in their support network are having. Girls who have higher levels of caring and are involved in the problems of their close friends are more vulnerable to depression (Gore, Aseltine, & Colten, 1993). Any negative experiences that a girl's best friend or members of her family are going through tend to add to her own negative mood. For example, one study found a significant link between mothers' emotional distress and their daughters' internalizing symptoms over the period from age 11 to 22. The same association was not found for adolescent boys and their mothers (Crawford et al., 2001).

Finally, adolescent girls may begin to experience numerous micro-aggressions in middle school and high school spawned by the sexist views of teachers, male peers, and even their parents. These negative messages create a picture of a world in which the adolescent girl is viewed as less important, less competent, and

Master-L/Shutterstock.com

Ironically, the fact that girls are likely to try to comfort and support their friends during periods of emotional turmoil makes them more vulnerable to negative moods and depression. How might adolescent girls protect themselves from this negative consequence of close friendships?

less entitled to her own independent views than her male peers. The result is increased feelings of insecurity, lack of confidence, and new feelings of worthlessness.

Depressed mood is of special concern during early adolescence for several reasons. First, it is associated with adolescent suicide. (For further discussion of adolescent suicide, see the **Applying Theory and Research to Life** box.) Second, depression is linked to alcohol and drug abuse. Adolescents who are struggling with strong feelings of depression may turn to alcohol or other drugs to try to alleviate or escape from these feelings. Third, adolescents who are depressed may be unable to participate effectively in the classroom, so their academic performance deteriorates. Finally, depression during adolescence may be a forerunner of severe depression later in adulthood.

Delinquency. **Delinquency** is an example of externalizing problems related to difficulties in controlling or regulating one's impulses. *Delinquent offenses* are actions for which an adult could be prosecuted. Then there are offenses such as truancy, running away, or underage drinking that are known as *status offenses*, which are illegal for adolescents. Many adolescents commit some type of delinquent act that goes undetected. For most young people, the fear and guilt that follow a delinquent act are usually enough punishment to prevent further violations.

In an examination of a 10-year period of delinquency cases handled by juvenile courts in the United States from 2004 to 2014, the number of cases declined by 37 percent (Furdella & Puzzanchera, 2015). Despite this promising decline, a substantial number of teens are involved in violent and property crimes. There were 38,414 teens under age 18 arrested for violent crimes and 173,500 teens arrested for property crimes in 2014 (Federal Bureau of Investigation, 2014). In a grey area, not listed as a crime, incidents of cyberbullying, harassment, and sexual intimidation among teens has become a focus in the field of violence prevention. According to the Youth Risk Behavior survey, 21 percent of girls and 8.5 percent of boys in grades 9 through 12 reported being electronically bullied in the past year (Kann et al., 2014).

Violent Teens. Not all teens who commit delinquent acts are involved in violent crimes or repeated offenses. In a longitudinal study of more than 4,500 high school seniors and high school dropouts in California and Oregon, more than half the sample reported being involved in violent behavior—65 percent of the boys and 41 percent of the girls. A subset of these youth, the repeat offenders, were persistently involved in violent acts and were also significantly more likely to be involved in other high-risk delinquent behaviors such as selling drugs, committing felonies, and using alcohol, marijuana, or other drugs. These extremely violent youths were also more likely to drop out of school and to have other mental health problems (Ellickson, Saner, & McGuigan, 1997). The teens who begin their delinquent behavior at a young age, do poorly in school and have low levels of school engagement, who are involved in drug use in middle school, and who hang out with peers who also use drugs are likely to engage in a pattern of increasing involvement in violence against others (Ellickson & McGuigan, 2000). Other studies implicate early negative childhood experiences, especially physical abuse, as a predictive factor of violent delinquent behavior among boys (Baglivio & Epps, 2016; van der Put & de Ruiter, 2016).

The idea that certain young offenders are more likely to follow a path toward continued violent crime makes decisions about sentencing especially troubling. Efforts to curb youth violence must pursue a differentiated approach—creating programs that are appropriate for the youth who engage in isolated acts of delinquency in their teen years and other interventions focusing on the serious offenders who have multiple problems and are likely to be involved in both aggressive behavior and antisocial delinquency well into their adulthood (Farrington, 2009).

Delinquency, especially acts against property or other people, is an expression of externalizing behavior. At his sentencing hearing, Trevor apologizes to the court and to the victim's family for his assault on a 5-year-old girl.

APPLYING THEORY AND RESEARCH TO LIFE

Adolescent Suicide

> I thought how easily you could kill yourself when you were drunk. Take a bath, fall asleep, drown. No turtle would come floating by to rescue you, no spotter plane would find you. I took my mother's knife and played johnny johnny johnny on the playhouse floor. I was drunk, stabbed myself every few throws. I held my hand up and there was satisfaction at seeing my blood, the way there was when I saw the red gouges on my face that people stared at and turned away. (Fitch, 1999, pp. 184–185)

Suicide at any age is deeply troubling, but adolescent suicide is cause for special anguish and soul searching. Public concern over adolescent suicide has been increasing in response to the rise in the suicide rate among adolescents. The suicide rate across all age groups in the United States, including those 15 to 24, has been increasing since 1999. Suicide is the second leading cause of death among adolescents ages 15 to 19. In 2013, there were 3,652 suicides in this age group, a rate of 8.3 deaths per 100,000 (Heron, 2016). These suicide rates may be underestimated, as there is a social stigma to reporting a death as suicide, and there are financial consequences to identifying a death as a suicide rather than as an accident. It is suspected that a significant number of adolescent deaths involving automobile accidents were actually suicides.

Death by suicide is only part of the picture. Every year, large numbers of young people attempt suicide or engage in self-harming behaviors. According to the Youth Risk Behavior Surveillance System report, 17 percent of high school students had seriously considered suicide and 8 percent had attempted suicide in the preceding 12 months (Kann et al., 2014). Girls are twice as likely as boys to attempt suicide, but boys are four times as likely as girls to die in a suicide attempt.

The rate of adolescent suicide differs by racial and ethnic groups. The risk of suicide death is substantially higher among American Indian and Alaskan Natives, especially the boys, than among other racial/ethnic groups. Suicide attempts are highest among American Indian and Alaskan Native girls. Differences in rates of suicide and suicide attempts across racial and ethnic groups suggest different risk and protective factors tied to culture, acculturation strains, exposure to stresses of poverty and community disorganization, the stigma of discussing mental health problems, and the strength of ties to a supportive community (Goldston et al., 2008).

Instances of suicides may be prompted by widely publicized suicides as well as by internal depression or as a reaction to humiliation or loss. In attempting to understand the causes of suicide, primary risk factors have been identified. These factors were reconstructed by studying the lives of adolescents who committed or attempted suicide. However, they may not be very useful in predicting whether a particular individual will commit or attempt suicide. Although depression and low self-esteem are often included in the profile of those who attempt suicide, they are usually coupled with other issues. Risk factors often come in combination with each other. The risk factors among adolescents include:

- Drug and alcohol abuse
- Mental health disorders, especially depression or schizophrenia
- A prior suicide attempt
- Family history of psychiatric illness or substance abuse disorders
- A victim of family violence, including physical, sexual, or verbal abuse
- Limited family or other close social support
- A family history of suicidal behavior
- A high number of stressful life events or recent losses, including discrimination, victims of bullying, or social rejection
- People who identify as a sexual minority
- Cultural values that discourage help-seeking
- The availability of a firearm
- Exposure to the suicidal behavior of others, including family, peers, in the news, or in fictional accounts

In addition to these factors, there is usually some precipitating event. Recent reports of teen suicides related to cyberbullying and sexting suggest a new context in which teens can experience humiliation. A shameful or humiliating experience, a notable failure, and rejection by a parent or a romantic partner are all examples. Use of drugs that alter cognitive functioning and decrease inhibitions, coupled with easy access to a gun, suggest one likely path from suicidal ideation to suicidal action.

Suicide and attempted suicide continue to be surrounded by social stigma for individuals and their families. Moreover, there is pervasive misunderstanding about the causes and possible approaches to prevention, thereby impeding efforts at intervention. The following *myths about suicide* illustrate these problems (Web MD, 2016):

1. *Discussing suicide might encourage it*. There is no evidence to support this statement.
2. *The only people who are suicidal are those who are mentally ill*. Suicidal thoughts may be an aspect of a mental illness. But many people who have mental illness are not suicidal; and not all people who attempt suicide have a mental illness.
3. *Individuals who talk about suicide won't really do it*. Talking about suicide may be a way to reach out for support or help. Any reference to thinking about suicide and any attempts at suicide should be taken seriously.
4. *There is no warning for suicides.* Suicide is usually accompanied by evidence of serious distress. There are warning signs that can be helpful in connecting a person who is thinking about suicide with appropriate help. However, it is very difficult to predict which people will attempt it.

The U.S. Department of Health and Human Services (2102) issued a monograph, *The 2012 National Strategy for Suicide Prevention: Goals and Objectives for Action*. A key premise of this monograph is that suicide is a public health problem that is preventable. Four action components of prevention include (1) creating supportive environments that promote healthy, empowered individuals and families; (2) strengthening clinical and community preventive services and reducing the stigma for seeking mental health services; (3) improving the availability of timely treatment and supportive services adapted to groups that are particularly at risk; and (4) improving data collection, research, and evaluation of suicide prevention initiatives.

A study of the impact of the Signs of Suicide (SOS) program in 92 schools demonstrated the potential impact of effective intervention. Students who participated in the program showed an increase in help seeking of 60 percent in the month following the introduction of the curriculum. School coordinators found no negative reactions among students who were exposed to information about suicide and suicide prevention, and some improvement in student and teacher communication following this intervention (Aseltine, 2003). A later replication, evaluating the program among ninth graders found a substantial decrease in reported suicide attempts, improved understanding of depression and suicide, more positive attitudes about intervening if a friend shows signs of suicidal intention, and more willingness to seek help for themselves (Schilling, Aseltine, & James, 2016). To learn more about suicide prevention, visit the website of the American Foundation for Suicide Prevention, or the Substance Abuse and Mental Health Services Administration of the U.S. Department of Health and Human Services.

Critical Thinking Questions

1. Propose an explanation to account for the fact that girls are more likely than boys to attempt suicide, but boys are much more likely than girls to die as a result of their attempts.
2. Evaluate the statement that suicide is a preventable public health problem. Why is suicide a public health problem? In your opinion, is suicide preventable? If so, what are the key steps to prevention? If not, why not?
3. Speculate about why school administrators, teachers, parents, and/or students might resist the implementation of an SOS program in their schools. What resources should schools and communities have available for teens and their families if they do implement such a program?

Risk Factors. A combination of biological, psychological, and societal risk factors are associated with delinquency. At the biological level, issues related to executive control, including impulsiveness, attention deficit disorder, and hyperactivity, are important considerations. The teen's neurological reward system is especially sensitive to social cues, especially the approval and encouragement of peers. Teens are more likely to engage in delinquent behavior when their peers are also involved in these kinds of activities. At the psychological level, issues of poor school performance, lack of empathy, a belief in the harmful intentions of others, and anxious-resistant attachment have been identified as predictors. At the societal level, childhood victimization, minimal parental supervision, modeling of criminal behavior of parents and other community adults, and an active criminal network in the community that recruits youth have all been identified as risk factors (Farrington, 2009). The neighborhood environment can play an important role in whether a teen engages in delinquent behavior. In a study that followed children in foster care, those who were relocated into neighborhoods characterized by greater poverty and instability had a greater likelihood of having a formal delinquency charge (Huang, Ryan, & Rhoden, 2016).

Delinquent Girls. Much of the literature on causes and characteristics of delinquent behavior has focused on boys. However, in 2004 the Office of Juvenile Justice and Delinquency Prevention created the Girls Study Group to understand more clearly girls' paths into delinquency, the way girls are treated in the juvenile justice system, and the risk and protective factors that can guide prevention programs. Results of this study group are published in *The Delinquent Girl* (M.A. Zahn, 2009). Although many of the same predictive factors are associated with delinquent behavior for boys and girls, a few factors seem to be particular to girls. Girls are exposed to a greater number of negative life events than boys and may be more biologically sensitive to the negative impact of stressors. Girls are more likely than boys to experience childhood sexual abuse and/or rape, which is predictive of subsequent depression, anxiety, and post-traumatic stress disorder. These mental health problems are implicated in subsequent delinquent behaviors. As a result of victimization, girls more than boys are likely to run away from home, which is a status offense. This often leads to other delinquent acts including prostitution, survival sex, and drug trafficking. Finally, early pubertal development is a risk factor, especially for girls in families that have ineffective parental monitoring or where affectionate bonds are disrupted through divorce, imprisonment, or desertion. Under these conditions, early maturing girls are more likely to engage in more risk taking, spend time with older peers who may encourage deviant behavior, and have older boyfriends whose influence may lead to engaging in delinquent behaviors.

Weapon Carrying. Within the larger context of delinquent and violent behavior, weapon carrying is a public health safety concern. As part of the National Youth Risk surveillance system, high school students are asked about their involvement in weapon carrying and experiences of being threatened by someone with a weapon. In 2015, 24 percent of male and 7.5 percent of female high school students said they carried a weapon at least one day in the past month. Six percent of students reported having been

In Austin, Texas, junior high school students go through a metal detector before entering their school. Teachers, students, and visitors are all subjected to this procedure.

Bob Daemmrich/The Image Works

threatened with a weapon on school property at least once in the past month (Kann et al., 2016).

Why do high school students carry weapons? In one analysis, teens who carried guns were found to differ from those who carried other weapons to school. Only three factors predicted carrying guns to school: having been involved in physical fights, knowing that one's peers have guns at school, and being male. The likelihood that boys would bring a gun to school increased as the incidence of gun ownership in the peer network increased, suggesting both fear of violence and a tendency toward violent behavior. In contrast, bringing other weapons to school was predicted by seven factors including having been in physical fights, knowing that peers carry guns, knowing about drug use among peers, knowing that that there were gang members at the school, skipping school, being male, and a perception that the school rules were unfair and not strictly enforced (Cao, Zhang, & He, 2008). In an effort to protect children from the violence associated with weapon-carrying, many schools have introduced metal detectors and security guards who screen all students as they enter the building.

Some authors suggest that many boys who commit violent crimes are suffering from a form of post-traumatic stress disorder that leaves them angry, disconnected from their feelings, and unable to anticipate or control overwhelming images of violence that surge up with minimal provocation (Slovak & Singer, 2001). Chronic exposure to violence has a disruptive impact on neurological development. Youth who are exposed to violence experience higher levels of symptoms associated with post-traumatic stress disorder, including difficulties regulating emotional reactions, difficulties concentrating, and difficulties inhibiting aggressive impulses. Exposure to violence also increases aggressive cognitions and the attribution of aggressive motives to others while, at the same time, lowering one's sensitivity to the pain and suffering of others. Prior victimization and exposure to violence clearly influence teens, increasing their fears and their involvement in weapon carrying as a way to protect themselves (Yun & Hwang, 2011).

In a reanalysis of the Youth Risk Behavior surveillance survey data, researchers examined the relationship of having been bullied at school and carrying weapons on school grounds. They considered several aspects of school-based intimidation including not going to school because they felt unsafe there, having had property stolen or damaged at school, having been threatened or injured with a weapon, and having been in a physical fight. Among students who had experienced one of these risk factors, 28 percent reported having brought a weapon to school; among students who experienced three or more of these factors, 62 percent brought a weapon to school. These data suggest a picture of weapon carrying for protection and/or retaliation (Kemp, 2014).

FURTHER REFLECTION: *Think back on your early adolescence, from the age of about 12 to the end of high school. Describe situations that made you feel happy, hopeful, competent, and self-assured. Describe situations that made you feel discouraged, angry, frustrated, or worthless. How would you characterize your emotional development during that time of your life? How did your emotions change over this period? How did your ability to express or control the expression of your emotions change? Four problem areas were discussed: eating disorders, depression, suicide, and delinquent behaviors. How aware were you of these problems when you were in high school? What, if any efforts were made to educate students about these topics?*

Membership in the Peer Group

OBJECTIVE 5 Analyze the nature of peer relations in early adolescence, especially the formation of cliques and crowds, and contrast the typical relationships with parents and peers during this stage.

The importance of peer interaction for psychosocial development is a continuous theme across the life span. Friendships, many of which are formed in middle childhood or even earlier, remain important in early adolescence. However, during early adolescence, the peer group becomes more structured and organized than it was previously and **peer group membership** becomes much more salient (Newman, 1982). Before the adolescent period, it is important to have friends but not so important to be a member of a definable group. A child's friends are often found in the neighborhood, local clubs and sports teams, community centers, or classrooms. It is not unusual for children whose parents are friends to become friends. And in many families, children identify their siblings and their cousins as their good friends. In early adolescence, young people spend more time away from home. Teens are more likely to interact with each other across classroom boundaries, leading to the formation of larger, more loosely affiliated friendship groups. Dyadic (two-person) friendships become an increasingly important source of social support, and the quality of these friendships changes. In addition to dyadic friendships, adolescents form small groups of friends, sometimes referred to as *cliques*, and in most communities they also become identified with a larger constellation of teens who have a common social identity, usually referred to as a *crowd* (Brown and Larson, 2009).

Cliques and Crowds

Cliques are small friendship groups of 5 to 10 friends. Usually, these groups provide the framework for frequent interactions both within school and in the neighborhood. Adolescents usually do not refer to their group of friends as a clique, but the term is used to connote a certain closeness among the members. They hang out together, know about each other's families, plan activities together, and stay in touch with each other from day to day. Within cliques, intimate information is exchanged and, therefore, a high degree of loyalty is expected. In the transition from middle school or junior high school to the larger, more heterogeneous environment of high school, there is a reordering of students according to a variety of abilities and a corresponding reordering of friendship groups. It may take some time for adolescents to find their clique, the members of which may change from time to time over the first year or two of high school. There is quite a lot of variability in the stability of the cliques; some dissolve over the course of a school year, and others remain intact throughout high school.

Crowd refers to a large group that can be recognized by a few predominant characteristics, such as their orientation toward academics, involvement in athletics, use of drugs, or involvement in deviant behavior. Crowds are more reputational than cliques, reflecting students' values and attitudes, preferred activities, and school and nonschool engagement. Students can typically name the crowds at their school, but when asked, not all students clearly fit with a specific crowd, and some students are in more than one.

Membership in a crowd at the high school may be based on one or more of the following characteristics: good looks; athletic ability; social class; academic performance; future goals; affiliation with a religious, racial, or ethnic group; special talents; involvement with drugs or deviant behavior; or general alienation from school. Although the criteria for group membership may not be publicly articulated, the groups tend to include or exclude members according to consistent standards. In a racially diverse sample of more than 600 middle school and high school students, some of the most common crowds mentioned were floaters (belonging to more than one group), nice or regulars, populars, middles (related to income), jocks, nerds/unpopulars, preps, skateboarders, and misfits/alternatives. Roughly 20 percent of the students said they did not belong to any group (Lohman, 2000).

In racially and ethnically diverse schools, it is not uncommon for students to identify crowds based specifically on ethnic categories, such as the Asian American group, the Mexican Americans, and the African Americans. Given the language diversity of some communities, adolescents may be drawn to peers who have a common home language. Banding together with other students who speak one's native language can provide a buffer from the direct or inadvertent stigma of limited English proficiency in a predominantly English-speaking school (Hill & Torres, 2010).

Crowds can be identified in a school setting by their dress, their language, the activities in which they participate, and the school settings in which they are most likely to congregate. For example, in one school, the crowds took their names from the places in the school where they hang out: "the fashionable 'wall people' who favor a bench along the wall outside the cafeteria, and the punkish 'trophy-case' kids who sit on the floor under a display of memorabilia" (Adler, 1999, p. 57). The peer culture in any high school is determined largely by the nature of the crowds that exist and their characteristic patterns of interaction. These large, visible groups provide an array of prototypical identities. Although many adolescents resist being labeled as part of one crowd or another, they usually recognize that these categories of students exist in their school. Thus, the youth culture, as it is sometimes called, actually comprises a number of subcultures, each endorsing somewhat different attitudes toward adults and other authority figures, school and academic goals,

Selfies provide a new way for members of a clique to preserve their "groupness". What better way to document a cohesive group of friends.

drugs and deviant behavior, and expressing different orientations toward partying and social life.

The relationship of crowd affiliation to behavior, especially behavior problems, has been established in research in the United States and Australia (Prinstein & LaGreca, 2002). In an effort to expand this picture to adolescents in Europe, researchers carried out a study of crowd affiliation in the Netherlands (Delsing, ter Bogt, Engles, & Meeus, 2007). The sample included over 2,000 adolescents ages 12 to 19 from 12 schools who self-identified as Dutch, Antillean, Moroccan, and Turkish. Adolescents were asked to rate how much they identified as a member of one of 10 crowds: punks, metal heads, Gothics, rural youth, Christian youth, normals, hip-hoppers, Rastas, elites, and brains. They also completed measures of aggression, delinquency, anxiety, and depression. The crowds could be differentiated on the basis of four dimensions: their orientation toward conventional or adult values; achievement and financial independence; urban youth culture, rebelliousness, nonconformity; and enthusiasm for rock music. Crowds whose members had a stronger conventional or achievement orientation also had lower levels of aggression and delinquency. Crowds whose members had stronger urban or alternative orientations also had higher levels of depression, delinquency, and aggression.

Group Boundaries and Norms

Membership in cliques is relatively stable but always vulnerable to change. Three processes contribute to the similarity among members of a clique: selection, socialization, and deselection. **Selection** refers to the idea that teens find other teens who share certain common interests, values, or preferences (e.g., teens who smoke find friends who smoke). **Socialization** refers to the idea that friends influence one another to behave in similar ways and to endorse similar views (e.g., teens who hope to go to college encourage each other to study, do well, and keep their grades up). **Deselection** refers to the idea that if an adolescent begins to differ from his or her friends on important behaviors or values, the relationships typically drift apart (Brown & Larson, 2009).

Cliques often have some central members who serve as leaders, others who are regularly included in clique activities, and still others who are on the periphery. At the same time, there are the "wannabes" who would like to be part of the clique but for one reason or another are never fully included. Some students try to push their way into a certain group; others may fall out of a group. Dating someone who is a member of a clique or getting involved in a school activity (such as athletics or cheerleading) may be a way of moving into a new peer group. A more likely scenario is that through gossip, refusal to adhere to shared group expectations, or failure in heterosexual relationships, individuals may slip outside the boundaries of their clique. Even when the specific members of a clique change, new members tend to have some common characteristics. Cliques of druggies find new friends who do drugs; cliques of jocks find new friends who excel in sports.

With the use of social networking, members of a crowd can maintain boundaries and solidify identity across a large group of "friends." By sharing photos, comments, gossip, information and misinformation, and by posting images or comments about new technologies, fashion, or fads as "legit," "fine," or "dope," members of the crowd can influence one another's values and behaviors. The instantaneous nature of online communication can accelerate peer contagion, influencing risky health behaviors, offensive sexual behaviors, gun ownership, and other forms of deviance (Bowes et al., 2015; Dishion & Tipsord, 2011). But the use of social media can also influence positive behaviors like attendance at school functions, enthusiasm for movies and books, volunteering, or civic engagement. Peers can use social media to embarrass or exclude, but they can also recognize and "call out" accomplishments of their friends. Texting with friends is a valued way that teens stay in touch on a daily basis. Among those who use social media, a majority say that they feel more connected to their peers' lives and daily activities, they feel better connected to their friends' feelings, and they have felt support from peers when they have been going through difficult times (Pew Research Center 2015d).

Changing one's crowd identity may be more difficult than changing from one clique to another. Adolescents appear to be on a trajectory toward certain crowd identities beginning in middle childhood. This trajectory is influenced by their athletic interests and competence, their academic abilities, their physical attractiveness, and their orientation toward authority (Stone et al., 2008). When the school population is relatively stable, it is more difficult to lose one's identity as a member of a particular crowd. In some schools, specific crowds have strong animosity toward each other. Members of the opposing crowds may occupy different areas of the school, participate in different activities, mock or ridicule each other, or articulate their differences in symbolic ways through dress, art, and music. When these differences are widely known, it becomes even more difficult to shift crowd identities. More research is needed about the contexts that permit changes in crowd membership and the motives that students might have for wanting a new crowd affiliation.

Membership in an adolescent peer group is a forerunner of membership in adult social organizations. As teens develop a focused peer group affiliation, they become aware of that group's internal structure and norms, as well as its relationship to other groups in the school environment. The existence of a complex peer structure in the high school environment and the motivation to find one's place within it puts pressure on the maturing mind to understand this structure. At the same time, maturing cognitive capacities permit adolescents to consider multiple variables and to speculate about hypothetical relationships. These abilities, newly stimulated by social motives, are now applied to an analysis of the high school peer structure. The structure may include patterns of social status, dominance, popularity, privilege, and relationships with others outside the group. Associated with each of these dimensions of social structure are sets of norms or expectations for the behavior of peer group members. As adolescents discover their positions in the dominance hierarchy of the group, they learn how they may advance within it and what behaviors are expected at various levels. On the basis of all this information, they must decide whether their personal growth is compatible with the peer group affiliation they have made.

Parents and Peers

Under optimal conditions, the increasingly important role of peer relationships in early adolescence takes place within a background of continuing close, supportive relationships with family members. Adolescents describe a variety of overt signs of independence from their families: They may make decisions about clothes, dating, and so on; they may drive cars; they may stay out late; and they may earn their own money. However, they continue to maintain an emotional attachment to their families and to family values. Support from this close inner circle made up largely of family members is an important correlate of well-being and sociability.

Parent–Adolescent Interaction.

Using the attachment paradigm as a frame of reference, one can think of adolescence as a time when young people strive to expand their range of exploration with reduced needs to return to the secure base. Adolescents try to decrease their dependence on their parents for setting goals, establishing patterns of tastes and preferences, and making decisions. This does not mean that the sense of closeness and connection with parents is less important. For example, adolescents may not want to seek help from parents when they are experiencing difficulty in their social relationships, but at the same time, if a serious problem arises, they want to know that their parent is available to be supportive and understanding. Adolescents who continue to experience parental warmth also report lower levels of emotional distress than those who report more distant relationships with parents and turn more to peers for support (Operario, Tschann, Flores, & Bridges, 2006). Adolescents can take the point of view of their parents. Although they may not always act as if they are aware, they realize when their behavior has been a source of distress to their parent, or if they have tested the limits of previously agreed-upon rules or boundaries. Within the context of a secure attachment, these times lead to a goal-corrected revision in the balance of autonomy and closeness. In many ways, the parent's desire to foster a child's self-reliance and a child's goal to reduce the parent's authority over day-to-day behaviors are compatible. In the process of achieving these goals, some loss of emotional closeness is likely (Allen, 2008; Collins & Laursen, 2006).

Parent–Adolescent Conflict.

As adolescents go through puberty, conflicts with parents are likely. One way of understanding this conflict is to view it as a way for adolescents to achieve new levels of individuation and autonomy while still preserving bonds of closeness and connection (Collins & Laursen, 2006). A meta-analysis of patterns of conflict in White, middle-class families found that frequency of conflict and intensity of conflict were two distinct dimensions. Over time, the frequency of parent–adolescent conflict decreased from early adolescence (ages 10 to 12) to middle adolescence (12 to 16), but the intensity of those conflicts increased (Laursen, Coy, & Collins, 1998). Typically parent–adolescent conflicts are about daily issues, like household chores, cleaning up their room, how money will be spent, whether the child is spending enough time on schoolwork, or curfews, rather than about basic value issues like political ideology or religious beliefs. This same pattern has been observed in African American and White middle-class families (Smetana, Daddis, & Chuang, 2003).

With age, adolescents and their parents expand the range of issues that are considered personal issues that should be decided by teens and not subject to parental authority, such as how they spend their free time, how they dress, or the kind of television shows they watch. Nonetheless, certain areas of morality or safety, like using drugs or smoking cigarettes, still fall under parental authority. Some issues, such as hanging around with people your parents disapprove of, may be topics that require negotiation. They are not clearly in the parental authority or the personal preference domain.

Even though the trend is for the domain of personal preference to increase with age, families differ both within cultures and across cultures in how likely they are to view decisions as legitimately governed by parental authority, personal adolescent preferences, or shared control (Cumsille, Darling, Flaherty, & Martinez, 2009). These differences in perceptions about who has legitimate authority around issues of concern to adolescents are relevant for the extent to which parents and children experience conflict, the extent to which adolescents try to deceive their parents, and the opportunities that parents have to influence their children's decision making. Consider the following narrative written by a Chinese adolescent whose family had recently immigrated to Canada (Li, 2009).

Tom & Dee Ann McCarthy/Corbis/Getty Images

Renee and her dad have a regular evening chess game. They have a relaxed conversation about other things while they play the game. The combination of competition, conversation, and companionship provides an important source of social support for both of them.

> My parents said we brought you to Canada because student life in China is too hard. But now I don't think my life has changed except for the place. I am still being pushed very hard. . . . They always press me like, "you should study, you should study, you should study. . . . like this." If I just watched TV for 10 minutes, by the 11th minute, they would say "go study, don't watch it" or they would say "if you are tired, you can rest for 5 minutes, then go back to your study." They say this to me almost every day. (Li, 2010, p. 488)

In European American families, as children get older, they are less likely to concede to their parents, and parents are increasingly likely to concede to their children. In African American families, most conflicts end with the child conceding to the parents, preserving the cultural value of obedience and respect for elders (Smetana, Daddis, & Chuang, 2003). In a study of Chinese American adolescents, expectations for personal autonomy seemed to be expressed at a somewhat later age. Urban Chinese American youth were more accepting of open disagreements with their parents than rural youth and described their relationships with parents as less cohesive and more conflictual than rural youth (Wenxin, Meiping, & Fuligni, 2006). Mild, periodic conflicts reflect a changing balance of power or control within the family, as adolescents give voice to their own opinions and defend their choices. The acceptability of these conflicts, their intensity and frequency, and the ways they are resolved appear to be shaped by the cultural context and values regarding individuation and interdependence.

One topic of special interest is parent–adolescent conflict about peer relationships. Parents use a variety of techniques to manage, monitor, and possibly control their adolescent children's peer interactions (Mounts, 2004). Whereas adolescents may seek parental advice from time to time about peer issues, they also view peer friendships, clique membership, and time spent with peers to fall into the category of personal choice. As they get older, adolescents are likely to defend their right to choose their friends and to spend time with friends as they see fit. In a study of an ethnically diverse sample of seventh and eighth graders, high levels of parent–adolescent conflict over peer relationships were associated with greater amounts of delinquent behavior, more drug use, and lower grades (Mounts, 2007). Because this was a correlational study, we do not know whether the parent–adolescent conflict is a result of the parents' assessment that the child's friends are antisocial and engaging in high-risk behaviors, or if the parent–child conflict about peers leads the child to seek out friends who are similarly distressed at home and resort to antisocial, high-risk behaviors.

Parenting and Peer Group Membership. The quality of the home environment, especially the nature of parenting practices, has implications for the adolescent's peer relationships. High levels of power assertion by parents are associated with a greater likelihood of peer rejection during middle childhood. Studies of the relationship of parenting practices to adolescent peer group membership extend this analysis. A model was proposed to examine the relationship of parenting practices to adolescent behaviors and ultimately to crowd affiliation (Brown, Mounts, Lamborn, & Steinberg, 1993; Durbin et al., 1993). Parenting practices were operationally defined as the extent to which parents emphasized academic achievement, parental monitoring of adolescent behaviors, and the degree to which parents involved adolescents in decision making. Three adolescent behaviors were measured: the students' grade point averages, drug use, and self-reliance. Finally, the students were identified as members of one of six crowds: popular, jocks, brains, normals, druggies, or outcasts.

Parenting practices had both direct and indirect impacts on adolescents' crowd memberships. Parenting practices were linked to the children's behavior, which in turn was a strong predictor of their crowd affiliation. Parents who emphasized academic achievement were likely to have adolescents who had high grades and who were self-reliant, factors that also predicted being popular and not being members of the druggie or outcast groups. Low parental monitoring and little joint decision making were associated with drug use, low self-reliance, and membership in the druggie crowd. Adolescents may perceive their involvement with their peers as a matter of personal preference that is separate and distinct from their family life. However, this research suggests that parental socialization practices and features of the home environment establish a trajectory for the adolescent's likely path toward peer relations.

FURTHER REFLECTION: *What are some lessons learned from high school peer relationships that continue to be meaningful to you today?*

The Psychosocial Crisis: Group Identity Versus Alienation

OBJECTIVE 6 Explain the psychosocial crisis of group identity versus alienation, the central process through which the crisis is resolved, peer pressure, the prime adaptive ego quality of fidelity to others, and the core pathology of isolation.

Throughout life, tensions arise between the desires for individuality and for connection. Certain cultures emphasize connection over individuality, whereas others put individuality ahead of connection. However, all societies must deal with both aspects of the ego: the *I* as agent, originator, and executive of one's individual thoughts and actions, and the *We* as agent, originator, and executive of collective, cooperative enterprises that preserve and further the survival of the group (Triandis, 1990). During the early years of adolescence, one confronts a new psychosocial conflict, in which pressures to ally oneself with specific groups and to learn to be comfortable functioning as a member of a group are major preoccupations. This conflict is called *group identity versus alienation* (Newman & Newman, 2001).

Group Identity

In early adolescence, young people form a *scheme*—an integrated set of ideas about the norms, expectations, and status hierarchy of the salient groups in their social world. They build these representations from **reference groups**, the groups of which they are members or in which they aspire to hold membership (Gurin & Markus, 1988). Associated with these schemes are strong emotional investments, cognitions, and possibly behavioral patterns. Young people may be viewed by others as belonging to certain groups—for example their racial, religious, academic, school, immigrant status, disability status, or neighborhood identities. You might consider these groups part of the young person's "social address." But these groups are not necessarily salient to the young person's group identity. As a young person prepares to engage in the larger social world, a positive sense of group identity provides confidence that he or she is meaningfully connected to society, has a cognitive map of the characteristics of the social landscape, and the skills or tools to navigate the terrain. Perceiving oneself as a competent member of a group or groups is fundamental to one's self-concept as well as to one's willingness to participate in and contribute to society. The formation of social commitments in early adolescence provides a foundation for the capacity to establish meaningful ties to groups at the personal, community, national, and international levels in adult life (Lawler, Thye, & Yoon, 2009).

Early adolescents experience a search for membership—an internal questioning about the groups of which they are most naturally a part. They ask themselves, "Who am I, and with whom do I belong?" Although membership in a peer group may be the most pressing concern, questions about other group identifications also arise. Adolescents evaluate the nature of their ties to immediate and extended family members, and they begin to understand the unique characteristics of their racial, ethnic, cultural, and sexual identities. They may become identified with various organizations (e.g., religious, political, civic).

In the most positive pattern, peer group membership does not replace attachment to parents or closeness with family. Rather, the adolescent's network of supportive relations is anchored in the family and expands into the domain of meaningful peer relationships. Adolescents who show strong signs of mental health and adaptive coping strategies have positive communication and trusting relationships with parents or other close family members as well as strong feelings of trust and security among their friends.

In the process of seeking group affiliation, adolescents are confronted by the fit—or lack of fit—between their personal needs and the norms and values of relevant social groups in the environment. The process of self-evaluation takes place within the context of the meaningful groups whose members are available for comparison and identification. Needs for social approval, affiliation, leadership, power, and status are expressed in the kinds of group identifications that are made and rejected during the period from age 12 to 18. In a positive resolution of the conflict of group identity versus alienation, adolescents discover one or more groups that provide a sense of group belonging, meet their social needs, and allow them to express their social selves.

Cognitive Processes That Support the Formation of Group Identity

Adolescence is not the first time that children are aware of being a group member or of claiming an affiliation with a group. Young children may be on sports teams, play in an orchestra or band, or belong to a dance group. They tend to define groups on the basis of common activities. In comparison, adolescents have a mental representation of the social groups in their school or community and the relationships among these groups. They are able to analyze the norms and expectations associated with various groups. They can assess the status or prestige of being a member of a particular group, and the ways that group membership affects attitudes and values, shapes interests, and influences one's self-concept through acceptance and rejection (Bettencourt & Hume, 1999). For example, in a high school, teens can identify various crowds and describe distinctions among these groups with regard to their dress, where they hang out at the school, and behaviors or values that are associated with these crowds. Further, adolescents can characterize what it would take to be a member of one of these crowds, the possibility of being in more than one of these crowds, the possibility for interactions among members of these crowds, and the advantages or disadvantages linked to being associated with each of these crowds.

Three cognitive capacities are needed for an adolescent to establish a group identity: (1) group representations, the conceptualization and labeling or classification of groups; (2) group operations, the processes through which groups are formed, maintained, or dissolved; and (3) reflective thinking about groups, an ability to analyze the array of groups and their relationship to one another.

Group Representations. Group representations provide the earliest forms of group identity, reflecting the ability to use words and symbols to signify membership in a group. Children have a wide variety of group experiences and are able to represent their group membership using verbal labels and drawings. The capacity for representing groups and the relationships among groups expands in early adolescence so that youth are able to map more groups simultaneously, including those in their immediate family, school, and peer environments. The expansion of this representational ability may be stimulated by exposure to a greater variety of groups, by increases in representational skills, and by new social demands to establish one's place within the range of existing groups. It may also be a product of neurological changes that accompany puberty.

Group Operations. Group operations include such diverse processes as joining a group, forming in-group and out-group attitudes, stereotyping, quitting or rejecting a group, and exercising leadership in a group. Some of these operations can be observed among toddlers and early-school-age children. They recognize the common members of a group, use fantasy play to coordinate roles with other members of a group, and talk about themselves as part of a family, school, or friendship relationship. Group operations can be observed in neighborhoods, with some children experiencing exclusion and others experiencing acceptance and support. Children as young as 5 or 6 may join sports teams and learn lessons of team spirit, teamwork, and team pride. By the fourth and fifth grades, some children have already begun to experience social isolation and social rejection. In early adolescence, teens develop more advanced skills for connecting to their groups, experiencing bonding and acceptance, participating in leadership and team building, and detecting evidence about the possibility of rejection from their significant groups.

Table 9.4 Four Types of Experiences that Build a Sense of Group Identity

Type of Experience	Explanation and Example
Categorizing people and recognizing features of group membership	Awareness of group boundaries and shared markers of members like use of symbols, jargon, or common activities.
Experiencing a sense of history as a member of a group	Continuous interactions over time that create shared knowledge and shared experiences.
Emotional investment in the group	In-group bias, investment in the group members, and efforts to preserve the group's social reputation.
Social evaluation of one's group and its relation to other groups	A capacity to analyze the social hierarchy of the groups in your school or community; to differentiate between how others view one's group and how you value it.

Reflective Thinking About Groups. The formation of group identity involves reflective and comparative thinking. It requires decentering from one's own groups to consider how these groups may be perceived by others, evaluating the strengths and weaknesses of a group, and considering the implications of group membership for how one is treated in the community. Early adolescence is characterized by a new consciousness about one's membership in groups, the boundaries and barriers that separate groups or limit membership in groups, and the social implications of being in one group or another. The emergence of formal operational reasoning brings new capacities for reflection and speculation about social relationships and complex social systems.

Four Types of Experiences That Build a Group Identity

Given the three cognitive capacities that permit the conceptualization of a group identity, we hypothesize that the actual formation of a group identity requires four types of experiences: (1) categorizing people into groups and recognizing the distinguishing features that define members, (2) experiencing a sense of history as a member of a group, (3) having an emotional investment in the group, and (4) detecting the social evaluation of one's group and its relation to other groups (Table 9.4).

Categorizing People and Recognizing Distinguishing Features of Group Members. Groups typically have *boundaries* that limit membership and *shared markers* that bind the members together. In early adolescence, young people learn to read, categorize, and relate to informal peer networks where clique structures provide a comparatively egalitarian learning environment, determine social status, and help define a person's feelings of belonging and worth. Language use, nonverbal gestures, style of dress, use of certain spaces, behaviors such as cigarette smoking or drug use, and participation in specific activities may become markers that delineate group membership and provide a sense of group identification. Having a symbol, a logo, or a tattoo can increase a group's visibility, give it a greater sense of reality, and convey the cohesiveness of the group (Callahan & Ledgerwood, 2016). Friends may invent expressions or unique ways of speaking that help define a group and strengthen members' commitment. Over time, the similarities among members of a peer group are strengthened, thereby clarifying their commitment to certain values and behaviors. Although much of the literature that explores this process has focused on deviant or risky behaviors, such as cigarette smoking, alcohol use, or truancy, the process can support prosocial commitments as well.

Experiencing a Sense of History as a Group Member. In a gym class, one may be assigned to the red team one day and to the gray team another. These assignments do not foster a meaningful sense of group identity. However, if one joins the band and practices every day, performs at games, travels on the bus, and parties with the band members, the sense of being a "bandie" begins to take shape. Group identity emerges out of continuous interactions, through which one becomes visible and known to other group members while they become visible and known to you. What was done in fun last year may become next year's tradition as a group selects rituals to symbolize how important they all are to each other. Participation in group rituals, whether of a formalized nature, like an initiation ceremony, or an informal nature, like a group outing to the beach to celebrate the end of school, contribute to the cohesiveness of the group. They foster cooperation among the group members and mark group boundaries. Teens who participate in group rituals, especially rituals that involve resources, challenges, pain or danger, or time consuming planning to enact, are likely to experience heightened commitment to the group (Watson-Jones & Legare, 2016).

Of course, memberships in groups change. One may transfer to a new school, join a new team or club, or become part of a group that gets together only in the summers. In each case, the formation of a sense of group identity requires the accumulation of interactions and the sense of having a history of shared experiences. Here one sees the interconnection of the *I* and the *We*. One may think of the *I* as the agent that seeks out group membership, choosing to join one group or avoid another. At the same time, as one participates in a group and experiences a sense of shared history, one begins to internalize values, beliefs, and practices held in common by the group, thus leading to a revision of the *I* and strengthening of the *We*.

Emotional Investment in the Group. The intensification of emotions that occurs with puberty and early adolescence is often evidenced in a deepening dedication and commitment to one's groups, including family and kinship groups. One sees here the seeds of nationalism and patriotism—a redirection of feelings of self-worth to the group and a binding of energy to the group as an extension of oneself. Evidence of this emotional investment

Anton Gvozdikov/Shutterstock.Com

These four friends are having a wonderful time joking, singing, and hanging out. They will look back on this special afternoon sitting in the big orange chair for a long time. It will provide a sense of shared history that will keep the group members emotionally invested in each other.

is found in the expression of pride about one's group, a tendency to idealize the members of the group in comparison to others outside the group, and a willingness to make personal sacrifices in order to support or advance the group's goals. The emotional investment can be expressed as positive feelings of attraction to other members of the group and negative feelings of depression or jealousy associated with betrayal.

Social Evaluation of One's Group and Its relation to Other Groups. Adolescents become aware of the status hierarchy of the groups in their school and neighborhood. They recognize how their groups are viewed by others, and they form their own views of each group's value and importance to them (Dunbar, 1997). A strong, positive identification with one or more groups, coupled with a sense of belonging to valued groups, are associated with improved feelings of well-being (Wakefield et al., 2016). The group identity established during early adolescence occurs in the context of a social reality in which one's own group can be located in a status hierarchy leading to judgments about the merits of the group and about oneself as a member of the group. Studies of racial and ethnic identity clearly show that adolescents are able to differentiate between being viewed negatively by others or being a target of discrimination, and expressing personal pride in their racial group (Williams & Thornton, 1998).

Ethnic Group Identity

One of the most challenging aspects of establishing group identity facing many adolescents is the formation of an **ethnic group identity** (Spencer & Markstrom-Adams, 1990). Ethnic group identity includes knowing that one is a member of a certain ethnic group, and recognizing that some aspects of one's thoughts, feelings, and actions are influenced by one's ethnic identity. One's ethnic group becomes a significant reference group, whose values, outlook, and goals are taken into account as one makes important life choices. Ethnic group identity varies across ethnic groups and among individuals within groups. For example, some young people have had more exposure to the cultural norms and values of their ethnic group than others. Some have had more guided parental socialization about the existence of prejudice and ways of coping with discrimination. Some children are born to mixed-race or multiracial parents, thus further complicating their definitions of ethnic group identity. Thus, ethnic group identity is more aptly viewed as a psychosocial rather than a demographic variable. It is based upon socially constructed meaning rather than biological or genetic differences (Ho, 2015; Phinney, 1996b; Quintana et al., 2006; Smedley & Smedley, 2005).

In the United States, a history of negative imagery, violence, discrimination, and invisibility has been linked to African Americans, Native Americans, Asian Americans, and Hispanic Americans. Young people in each of these groups encounter conflicting values as they consider the larger society and their own ethnic group identity. They may struggle with the negative or ambivalent feelings that are linked with their own ethnic group because of the cultural stereotypes that have been conveyed to them through the media and their schools, and because of the absence of role models from their own group who are in positions of leadership and authority.

Issues of ethnic group identity may not become salient until early adolescence. As children of color grow up, they are surrounded by members of their own ethnic group and socialized to internalize the values and beliefs of that group. At the same time, through participation in school, exposure to the media, and exploration of their community, they incorporate many of the ideals and values of European American culture. Several longitudinal studies describe a trajectory of development of racial/ethnic identity across adolescence (Altschul, Oyserman, & Bybee, 2006; Pahl & Way, 2006). With more advanced social and cognitive abilities, adolescents who are members of ethnic minorities are likely to think of themselves as bicultural or multicultural. This is most likely in school environments that are diverse and when teens experience peer acceptance in a multiracial/ethnic friendship group (Rutland et al., 2012).

In the transition to high school, adolescents may encounter more evidence of discrimination through overt rejection, academic hassles, being ignored, being harshly punished, or experiencing fewer opportunities to be recognized for school leadership roles (French, Seidman, Allen, & Aber, 2000; Seaton, Yip, & Sellers, 2009). In some communities sanctions against cross-race/cross-ethnic friendships and dating relationships may become more intense.

The nature and extent of racial or ethnic hostilities are related in part to the composition of the high school. In some schools, ethnic group hostilities are accentuated by their convergence with other attitudes and values, like academic engagement, athletic participation, or economic resources (Laursen et al., 2010). Students who are in a racial or ethnic numeric minority within their school are more likely to experience intergroup hostilities than those who are in a more diverse, well-balanced school (Graham, 2004, 2011). Students may find that their family and ethnic group values conflict with the values of the majority culture. Acculturation strain may stimulate new levels of exploration and ethnic commitment, or new sentiments of alienation. During the high school years, most youth are in the process of exploring what their ethnic group membership means to them, not yet having made a clear commitment to embracing or crystallizing an ethnic identity (Yip, Seaton, & Sellers, 2006).

It is not uncommon to observe a gradual unfolding of ethnic identity as adolescents move from unexamined assumptions about their ethnic group to greater degrees of exploration, analysis, comparison, possible confusion, and eventual commitment to a version of ethnic group identity that fits with their other group identities. In a longitudinal study of Latinos' ethnic identity over a 4-year period, girls showed a steady growth in exploration of their ethnic identity, increased clarity about what their ethnic identity meant to them, and increasingly positive feelings about their Latina identity. For boys, there was little evidence of exploration or increased clarity, but there was growth in the positive feelings about being Latino. For both boys and girls, affirmation of their Latino ethnicity was positively associated with self-esteem (Umaña-Taylor, Gonzales-Backen, & Guimond, 2009).

In the transition from early to late adolescence, most minority youth experience some critical evaluation of the values and beliefs of the dominant culture and how they conflict with the values and beliefs of their own ethnic group. The more fully immersed young children are in the values and traditions of their ethnic heritage, the more likely it is that they will experience a *dual* or *multiple identity*—for example, seeing themselves as both American and African American or American and Chinese American (Phinney, 1997). Over time, and with the benefit of exposure to reading, conversations, and interactions with people from other subgroups, young people begin to synthesize a sense of how their ethnic identity fits into their overall personal identity and how it will influence the quality of their relationships with members of their own and other ethnic groups (Cross, 1991; Phinney, 1989, 1996; Yip, Seaton, & Sellers, 2006).

Most research on ethnic identity in the United States has focused on African American, Latino American, and Asian American youth. Relatively little attention has been given to the ethnic identity of the racially/ethnically privileged European American youth. There are substantial benefits to being a member of a racially/ethnically privileged group for social status, access to resources, and social expectations. Not much is known about how these benefits and their link to being a member of a privileged racial/ethnic group are conceptualized by European American youth (Spencer, 2006). One study examined how the ethnic label that White children gave themselves related to their attitudes toward other minority groups. Those White children who considered themselves biracial, or of some hyphenated ethnic identity (e.g., Greek-American or Polish-American) showed less in-group and out-group bias than those who viewed themselves as singularly White or American (Brown, Spatzier, & Tobin, 2010). This finding provides further evidence of the simultaneous emergence of the *I* and the *We* as part of group identity.

Huntstock/Jupiter Images

For these Chinese American teens, their ethnic identity is integrated into their personal identity as they form friendships and make commitments to their families and community.

Alienation

Alienation refers to a sense of social estrangement, an absence of social support or meaningful social connection. Alienation at the individual level may result from societal norms and biases when individuals are denied resources or access to participation based on some aspect of their group identity. This type of exclusion can be experienced early in childhood when children are rejected from play groups or school activities. It can expand in middle childhood and early adolescence through barriers to educational or community resources. Family and community norms can create an environment in which some children emerge into early adolescence with a history of rejection and victimization due to their group identity (Killen, Elenbaas, & Rutland, 2016).

Alienation may arise from dilemmas associated with issues of **common identity**, **common bond**, or both. Alienation associated with issues of common identity may happen when young people are forced to take on roles or are expected to comply with group expectations to which they do not subscribe. This might occur as a result of stereotyping, racism, or elitism within a school or community. For example, in a study of Muslim adolescents ages 12 to 18, 84 percent said they experienced one or more acts of discrimination in the previous year, and 10 percent reported daily discrimination (Sirin & Fine, 2008). In the current political climate, with the president elect being very outspoken in his views against Muslims, teachers and students report heightened levels of hostility toward Muslims and fearfulness among Muslim students (Costello, 2016). In many schools, some subsets of students are marginalized due to some marker such as minority status, physical disabilities, or developmental delays, or as a result of poor social skills or low academic motivation. These students are often typed as nobodies, loners, disengaged, or outcasts.

Alienation associated with issues of common bond surfaces when adolescents are unable to form interpersonal ties that provide feelings of acceptance and emotional support. Under conditions of parental coldness, distancing, neglect, or rejection, children find that they cannot count on the family to serve as a source of emotional or instrumental support (Dishion, Poulin, & Medici-Skaggs, 2000). They lack a template for experiencing the foundational benefits of belonging that are associated with group identity. As a result of harsh parenting, some adolescents have poor social skills—they are either overly aggressive and domineering, or overly withdrawn and socially inept (Poulin, Dishion, & Haas, 1999). Over time, children with poor social skills are less likely to form satisfying social relationships with friends and are more likely to engage in delinquent behaviors that reflect their sense of alienation from family and peers.

In some families, children are exposed to a pattern of hostile, aggressive parenting in which the custodial parent insists in the most assertive and unkind way that their other parent is someone to be mistrusted, an enemy to be avoided and disrespected. This condition, referred to as **parental alienation** (PA), is defined as follows:

> a mental condition in which a child, usually one whose parents are engaged in a high-conflict separation or divorce, allies himself strongly with one parent (the preferred parent) and rejects a relationship with the other parent (the alienated parent) without legitimate justification. PA features abnormal, maladaptive behavior (refusal to have a relationship with a loving parent) that is driven by an abnormal mental state (the false belief that the rejected parent is evil, dangerous, or unworthy of love). (Bernet & Baker, 2013, p. 99)

These efforts to alienate a child from a parent are frightening, confusing, and a source of emotional distress. The child, exposed to this kind of emotional abuse, may experience a variety of symptoms such as anxiety, withdrawal, self-inflicted injuries, or uncontrolled aggression, any of which may make the establishment of effective peer relationships difficult. As the child gets older, he or she may question or challenge the hostile, aggressive parent, asserting his independent view about the absent parent and defying the custodial parent. The child may reach adolescence alienated from both the noncustodial parent and the custodial parent and lacking the social skills needed to form satisfying peer friendships (Baker, Burkhard, & Kelley, 2012).

Conditions that create parent–child alienation can spill over to impact children's mental health, school performance, and peer relationships. Evidence of parent–child alienation has been observed in some immigrant families where conflicts arise due to differences in the acculturation process for children and families. Having brought their children to a new country, some parents then proceed to withdraw support and become increasingly critical as their children embrace new, American values. The result is not only alienation within the parent–child relationship but also problems for the adolescents related to health, non-engagement with school, and feelings of depression and hopelessness (Cheng et al., 2013; Kim et al., 2013; Wang & Benner, 2016).

Alienation may result from personality characteristics, such as shyness, introversion, or lack of sociability. Some young people experience social anxiety, mistrust, or cautiousness that prevent them from forming interpersonal connections. Others are overly self-conscious, so preoccupied with their own feelings and thoughts that they withdraw from social interactions. Feelings of shame over an illness, disability, or perceived inadequacy may lead to perceptions of peer rejection or an unwillingness to form social bonds (Fife & Wright, 2000). Some teens who are alienated from peers in their face-to-face social environment may become invested in virtual relationships through various social media in order to satisfy their needs for peer group connections (Xu & Zhang, 2011). Social media can also serve as a vehicle to reinforce alienation, especially when teens block or "unfriend" a former friend, thus disconnecting them from their social network (Pew Research Center 2015d).

Finally, alienation may result from a combination of problems with common identity and common bond. For example, friendships across racial groups may be very difficult to preserve in a neighborhood but are supported in the school environment. If an African American and a European American adolescent become close friends at school, both may feel alienated from their same-race peers in their community. Youth who are recent immigrants may experience this conflict as they become acculturated. They may become increasingly distant from their families as they take on U.S. language and practices, but they may still be unable to form close, supportive relationships with U.S. adolescents who view them as outsiders. Nataša, an immigrant from Bosnia, described her experiences of alienation as a high school student:

> I was so different and so odd. I ended up in an all-girls Catholic school in the middle of Ohio where everyone is blond and everyone wants to get married and have babies.... And no one wanted to talk to me; *no one even wanted to talk to me*. I was the only person in the class that no one ever talked to because I'm so different, and they all made a point of seeing me as different. (Mosselson, 2009, p. 463)

In this case, Nataša's alienation is in part a result of her cultural displacement and the related lack of common identity and in part a result of the lack of common bond with other students in her school.

The Contribution of Alienation to Group Identity and Individual Identity

To some degree, experiences of alienation are important for the continued formulation of both group and individual identity. A period of feeling alone and lonely may help teens appreciate how good social acceptance feels and how important it is for their well-being. Moreover, experiences of alienation within a group may help a young person see the *I* against the backdrop of the

We. The discomfort of not fitting in helps one recognize the distinctiveness of one's point of view. In the extreme, however, the lack of social integration that may result from a negative resolution of this crisis can have significant implications for adjustment to school, self-esteem, and subsequent psychosocial development. Giving the important role of a sense of belonging for adaptation and well-being, chronic conflict about one's integration into a meaningful reference group can lead to lifelong difficulties in areas of personal health, work, controlling anger, and the formation of intimate family bonds.

The Central Process: Peer Pressure

Adolescents' family backgrounds, interests, and styles of dress quickly link them to subgroups of peers who lend continuity and meaning to life within the context of their neighborhoods or schools. The peer group social structure is usually well established in most high schools, and members of that structure exert pressure on newcomers to join one peer group or another. **Peer pressure** refers to demands for conformity to **group norms** and a demonstration of commitment and loyalty to group members. Young people outside the groups form expectations that reinforce adolescents' connections to specific peer groups and prohibit their movement to others. An individual who becomes a member of a group is more acceptable to the social system than one who tries to remain unaffiliated and aloof.

The term *peer pressure* is often used with a negative connotation, suggesting that young people behave in ways that go against their beliefs or values because of a fear of peer rejection. However, we suggest an alternative meaning that highlights the emerging role of the peer group in the radius of significant others. The pressure from those close by—those with whom a young person interacts each day—is not necessarily perceived as oppressive or coercive. It is, more often, the subtle co-adaptation of those who interact in the same social space, shaping and guiding one another toward intersubjectivity, much as an infant and a caregiver achieve mutual regulation. In a process of give and take, friends adapt to each other's preferences and interests, leading to a shared outlook on their world. We often read that the presence of peers can increase risk taking, especially when peer approval accompanies dangerous or hazardous actions. However peers can also encourage exploration and learning. When faced with new or challenging tasks, the presence of friends can improve learning, enhance exploration, and increase sensitivity to potential benefits of engaging in new behaviors. For example, Ellen is very shy, but it's Friday night and her good friend Pam wants to go to the basketball game and then to a party afterward. Ellen is reluctant. She knows there is often a lot of drinking at these parties, and she is not in with the popular crowd that usually goes to these parties. Pam promises her that she won't drink at the party and that if Ellen is really not having a good time Pam will leave with her. Ellen decides to go along with Pam and they end up having a very good time. Pam keeps her promise of no drinking, and at midnight they leave so they are home by their curfew. Pam and Ellen are now thinking about having a party at Ellen's house next week since this turned out to be a lot of fun.

Five modes of peer influence serve to encourage some behaviors and discourage others (Brown, Bakken, Ameringer, & Mahone, 2008). The most overt mode is the direct suggestion that a teen should perform a behavior (e.g., smoke marijuana) or risk group rejection. This is the usual connotation of peer pressure, and parents or educators are often focused on helping teens resist this type of influence. A second type of peer influence occurs through modeling. Teens who spend time with one another watch each other's style of dress, gestures, and use of language, and imitate those behaviors in an effort to consolidate their sense of group membership. A third type of influence is more subtle normative regulation, where peers use teasing, gossiping, or sarcasm to influence each other's attitudes and behavior. A fourth type of influence includes the many ways that peers reinforce one another's behaviors. Positive verbal statements, gestures like smiling, nodding, or giving "high fives," and Internet reinforcement such as "liking" on Facebook are all ways that teens convey encouragement for one another's behaviors. Among the teens who use social media, many report that they feel some pressure to post only content that will be viewed positively and make a good impression on their peers or to post content that will get lots of positive comments (Pew Research Center 2015d). Finally, peer influence occurs when friends create opportunities for unsupervised activities—having parties where beer is served, cruising in cars, or arranging to meet at a park or mall when adults are not likely to be present.

acestock/Alamy Stock Photo

These teens influence each other's style of dress and facial expressions. They show solidarity by wearing their hoods up when they walk the streets. Even on a crowded street, people can sense that they are together.

Affiliating with a Peer Group

The process of affiliating with a peer group requires an adolescent to accept the pressure and social influence imposed by it. This process provides the context in which the crisis of group identity versus alienation is resolved. Adolescents are at the point in their intellectual development when they are able to conceptualize themselves as objects of expectations. They may perceive these expectations as forces urging them to be more than they think they are—braver, more outgoing, more confident, and so forth. These expectations help define the zone of proximal development for group skills and social competencies. Peer pressure may have a positive effect on the adolescent's self-image and self-esteem, serving as a motive for group identification. Those dimensions of the self that are valued by one's own peer group become especially salient in each young person's self-assessment.

As members of peer groups, adolescents have more influence than they would have as single individuals; they begin to understand the value of *collective enterprise*. In offering membership, peer groups expand adolescents' feelings of connection and protect them from loneliness. When family conflicts develop, adolescents can seek comfort and intimacy among peers. For adolescents to benefit in these ways from their affiliation with a peer group, they must be willing to suppress some of their individuality and find pleasure in focusing on the attributes they share with those peers.

Conflicts Between Belonging and Personal Autonomy

Peer groups do not command total conformity. In fact, most peer groups depend on the unique characteristics of their members to lend definition and vigor to the roles that emerge within them. However, the peer group places importance on some level of conformity in order to bolster its structure and strengthen its effectiveness in satisfying members' needs. Indeed, most adolescents find some security in peer group demands to conform. The few well-defined characteristics of the group lend stability and substance to adolescents' views of themselves. In complying with group pressure, adolescents have an opportunity to state unambiguously that they are someone and that they belong somewhere (see the **Applying Theory and Research to Life** box Gangs).

Adolescents may also find that some peer expectations conflict with their personal values or needs. For example, they may feel that intellectual skills are devalued by the peer group, that they are expected to participate in social functions they do not enjoy, or that they are encouraged to be more independent from their families than they prefer to be. In most cases, adolescents' personal values are altered and shaped by peer group pressure to increase their similarity with the other group members. If, however, the peer group's expectations are too distant from the adolescents' own values, establishing a satisfying group identification will become much more difficult. As a result, adolescents experience tension and conflict as they try to balance the allure of peer group membership with the cost of abandoning personal beliefs.

Susceptibility to coercive peer pressure seems to peak at age 13 or 14, when adolescents are most sensitive to peer approval and make the initial transition toward new levels of behavioral autonomy and emotional independence from parents (Lamborn & Steinberg, 1993; Urberg, Shyu, & Liang, 1990). During the years from 14 to 16, adolescents become more adept at resisting peer pressure. Through encounters with peer pressure and opportunities to see how it feels to conform or resist, they develop a growing appreciation for the content of their personal values against the backdrop of peer expectations. However, if the emotional costs of identifying with the peer group become too great, adolescents may not open themselves up to group pressures. An inability to reduce the tension and conflict between group pressure and personal values produces a state of alienation in which the individual is unable either to identify with social groups or to develop personal friendships.

The Prime Adaptive Ego Quality and the Core Pathology

Fidelity to Others

A positive resolution of the psychosocial crisis of group identity versus alienation results in the achievement of the prime adaptive ego quality referred to as **fidelity to others**—a capacity to freely pledge one's loyalty to a group and to sustain one's faithfulness to the promises and commitments one makes to others. Fidelity to others produces the sentiments that are necessary to preserve small groups and larger communities alike: dedication to family, civic pride, and patriotism. One of the by-products of fidelity to others is *mattering*, a "feeling that others depend upon us, are interested in us, are concerned with our fate" (Rosenberg & McCullough, 1981, p. 163). Mattering is a relational aspect of the self-concept that reflects an assessment of how aware others are of you, how important you are to others, and how much others rely on you (Elliott, Kao, & Grant, 2004). When we pledge ourselves to others, we also become salient for them. We make a difference in their lives, and that, in return, contributes to our sense of well-being (Taylor & Turner, 2001). Adolescents who perceive that they matter to their parents and friends report higher levels of well-being than those who matter only to their parents, or to neither group (Marshall, 2004). For adolescents, mattering is closely related to self-esteem. When adolescents believe that they matter to important others, especially their families and close friends, they are less likely to engage in antisocial behavior, experience less depression, and are less likely to have suicidal thoughts (Elliott, 2009; Elliott, Colangelo, & Gelles, 2005). The Applying Theory and Research to Life box on gangs illustrates how the desire for mattering may lead a young person to make an affiliation with a dangerous or deviant group where they feel valued and protected, when those needs that are not being met by family, school, or other community groups.

Looking ahead to subsequent life stages, one can appreciate the significant role that this ego quality plays in pledging long-term faithfulness to friends, marital partners, children, one's aging parents, and other groups. Research on factors that buffer the

APPLYING THEORY AND RESEARCH TO LIFE

Youth Gangs

In the late 1920s and 1930s, the study of delinquency included an analysis of the role of youth gangs. Early on, it was understood that delinquent behavior was typically group behavior, involving two or more boys in some type of criminal activity. Gangs were viewed as social groups, not unlike the kinds of groups that boys in more stable, prosperous neighborhoods create.

The motives for joining a gang—"desires for recognition, approbation, and esteem of his fellows, for stimulation, thrill, and excitement, for intimate companionship, and for security and protection" (Burgess & Bogue, 1967, p. 300)—do not differ much from the motives that adolescents have for joining any type of social group or club. However, the focus of these gangs developed a delinquent emphasis and tradition that was passed from one generation of gang members to the next in a neighborhood. The ethical standards and values of these groups were often contrary to conventional values. In fact, actions that might bring a nondelinquent boy dishonor or shame—such as being arrested, appearing in juvenile court, or being sent to a correctional institution—would be viewed as a source of pride and distinction to a gang member.

Street gangs and youth gangs are defined as groups with membership ranging from early adolescence through about age 24. They are differentiated from motorcycle gangs, prison gangs, and ideological or hate-based gangs, which have mostly adult members. Street gangs are groups that have a history over many years, even many generations, a relatively large membership, an organization that usually includes a leadership hierarchy, and involvement in various violent crimes typically committed in a neighbourhood or territory (Howell & Moore, 2010).

Gangs continue to thrive in communities all across the United States. According to a survey carried out by the National Youth Gang Center, 3,100 jurisdictions experienced gang problems in 2012. Based on this survey, there are 850,000 gang members in 30,700 gangs across the United States. There has been a spread of gang activity over the years into small cities and suburban and rural jurisdictions; however, the greatest amount of gang activity and serious gang crime occurs in large cities. Gang-related homicides (n=2,363) increased by more than 20 percent in 2012 compared to the previous 5 year average, accounting for 16 percent of all homicides nationally in the United States (Egley, Howell, & Harris, 2014).

Gangs flourish in the most disadvantaged neighborhoods where social institutions such as families and schools are inadequate and opportunities are limited. They are organized to dominate their neighborhood territories, and, as a result, they reflect the ethnic composition of their neighborhoods. Youth gangs are therefore typically segregated by racial and ethnic groups. Teens in these neighborhoods also have a lot of free time; many are in neither school nor work. For gangs to be established and persist over time, youth must have limited access to appealing conventional jobs and career paths. Finally, there must be a place for youth to congregate, often an unsupervised park, mall, or street (National Gang Center, 2013, 2016).

Gangs may actively recruit new members, engage in violent acts of initiation, and are becoming increasingly associated with drug trafficking and violent crime. Yet, few gangs are actually involved in the coordinated sale and distribution of drugs. Rather, individual gang members become involved in the sale of drugs, which then may lead them to related violent crimes. Most of the violence experienced by gang members is linked to rivalries and territorial disputes between gangs. Although we tend to think of gangs as predominantly male groups, many decades of research have documented that females have been involved in gangs, both female gangs and adolescent girls who are members of mixed-sex gangs (National Gang Center, 2016).

Jeff Greenberg/PhotoEdit

These young gang members give hand signals to convey their gang membership, send messages to each other, and taunt or "dis" other gangs.

Young people may join gangs for a variety of reasons. *Pulls* that attract youth to gangs include "the perception of increased reputation and social status, the desire to be with friends and/or family who are already gang-involved, the promise of money, drugs, and/or excitement, and cultural pride and identification with one's neighborhood." .In contrast, some youth are *pushed* into gangs, possibly because of high levels of neighborhood crime, where they are coerced into joining or join because they hope to find protection within the gang (National Gang Center, 2016).

Adolescents who join gangs are often unsuccessful in school and may have been suspended or expelled. School failure leads to periods of unsupervised time in the community and an inability to find work. Modern gang activities are supported by a growing and spreading drug trade, easy access to guns, and the technology of cell phones with texting and voice mail, which allow gang members to coordinate their activities and preserve control over a wider area with increased mobility (Howell & Griffiths, 2016).

The concept of gangs is closely linked to the theme of group identity. Although gangs may have a violent, criminal, or antisocial value system, they provide a highly organized group for identification. Gangs have clothing, colors, symbols, and signs that provide recognition across settings. Being recruited into a gang may make a young person feel valued and protected by the older gang members. Despite the great risks associated with gang activities, the pervasive presence of gangs across all ethnic groups and diverse communities suggests that gangs address a number of needs that are not being met by communities, schools, and families.

To learn more about gangs and ideas about preventing adolescent involvement in gangs, visit the website of the National Gang Center sponsored by the U.S. Office of Juvenile Justice and Delinquency Prevention.

Critical Thinking Questions

1. Analyze the differences between being a gang member and being part of a clique or friendship group that is involved in delinquent activities. Describe the ways that gangs are similar to other kinds of tough or antisocial peer groups; describe the ways they are different.
2. Summarize the functions that are served by gang membership. Are the effects of gang membership only negative?
3. Evaluate how concepts presented in the chapter related to peer group membership and group identity versus alienation inform your understanding of gang membership.
4. Imagine that you are a school counselor, and a student has been brought to your attention who is suspected of being involved in criminal activity. Apply ideas from this chapter to develop an approach to working with this student to keep them engaged in school and to prevent future illegal behavior.

effects of stress often cite the contribution of social support to the long-term abilities of individuals to cope with change and to adapt positively to life challenges. Social support implies a capacity for fidelity. People who function as sources of support have the ability to remain compassionately connected to others during periods of hardship and loss as well as during periods of success and prosperity. When one thinks of a true friend, one pictures someone who stands by you even when it is not especially advantageous to do so. A true friend is someone who cares about you and supports you during moments of adversity as well as in times of joy.

Fidelity to others becomes a source of family solidarity as family members age and adults are called on to meet the needs of their own aging parents. The role one plays in caring for one's aging parents is largely voluntary. It is based on one's own definition of filial obligation, a sense of duty and responsibility for one's parents. Surely the way adults enact this role reflects their capacity for fidelity to others.

Dissociation

Dissociation refers to a sense of feeling removed and separate, withdrawal from others, and an inability to experience the bond of mutual commitment. It does not mean a preference for being by oneself, but rather a tendency toward social distancing and a reluctance to make the kinds of commitments to others that are required for the establishment and maintenance of enduring friendships and group memberships. Dissociation may involve a mental process that reflects lack of connection or continuity among thoughts, feelings, and actions. The following is an example of an adolescent who describes herself as floating along, disconnected from reality. Dissociation may be a symptom of more serious mental health problems such as schizophrenia, or an acute reaction to stress such as exposure to violence, rejection, or loss.

> What can I tell you about that time in my life? Hunger dominated every moment, hunger and its silent twin, the constant urge to sleep. School passed in a dream. I couldn't think. Logic fled, and memory drained away like motor oil. My stomach ached, my period stopped. I rose above the sidewalks, I was smoke. The rains came and I was sick and after school I had nowhere to go. (Fitch, 1999, p. 201)

Dissociation may occur as a result of rejection, abuse, or neglect. Adolescents who experience dissociation are likely to mistrust their peers and may even develop an attitude of hostile resentment toward the amiability and companionship they observe in others. Over time, dissociation results in the formulation of a mental world that is not well coordinated with social reality. A young person who experiences dissociation is likely to feel misunderstood and to lack confidence in her ability to communicate with or connect to others.

At a basic level, any sense of *we*-ness requires a shared understanding between at least two people and recognition that they experience some bond of investment in or identification with a common reality. This common reality could involve facing a common enemy, encountering a common crisis, or embracing a common goal. The core pathology of dissociation occurs when the young person is unable to experience the level of mutual understanding or symbolic connection that creates such bonds of *we*-ness.

FURTHER REFLECTION: *How do the developmental tasks of early adolescence contribute to the capacity for forming group identity? The psychosocial crisis of group identity versus alienation is closely linked to the issue of intergroup relations. Analyze the forces in schools or communities that foster positive intergroup relations among adolescents. What factors promote intergroup hostilities? Propose a strategy to promote positive intergroup relations at the middle school and high school levels. Trace the path of social development from infancy to early adolescence. What experiences from earlier stages might result in the negative resolution of the psychosocial crisis of group identity versus alienation?*

Applied Topic: Adolescent Alcohol and Drug Use

OBJECTIVE 7 Apply your understanding of developmental issues of early adolescence to an analysis of factors that account for patterns of adolescent alcohol and drug use.

American high-school-age youth show a higher level of illicit drug use than those of any other industrialized nation. By their senior year in high school (typically ages 17 and 18), almost half of American high school students have tried an illegal drug in their lifetime—whether marijuana/hashish, amphetamines, heroin or other opiates, cocaine/crack, methamphetamines, tranquilizers, or barbiturates (Johnston, O'Malley, Miech, Bachman, & Schulenberg, 2016).

FIGURES 9.6 a and b ▶ provide a historical overview of the lifetime prevalence of illicit drug use for 8th,10th, and 12th graders from 1975 to 2015 based on the *Monitoring the Future* national survey sponsored by the National Institute on Drug Abuse (Johnston et al., 2016). Following a period of decline from 1981 through 1992, drug use among adolescents increased over the 1990s and then began a second decline. Recent versions of the survey have identified the use of certain prescription and over-the-counter drugs for nonmedical use such as Adderall, Vicodin, Percocet, OxyContin, and cough medicines containing dextromethorphan.

Underage drinking is a serious public health concern. Alcohol is widely used by teens and is associated with a range of health and safety risks. In 2015, 26 percent of eighth graders had tried alcohol, and 11 percent said that they had been drunk at least once in their lives; 19 percent had tried a flavored alcoholic beverage. By the 12th grade, 64 percent had tried alcohol, 47 percent had gotten drunk, and 56 percent had tried a flavored alcoholic beverage. About 17 percent of 12th graders had experienced binge drinking (five or more drinks in a row) in the past

two weeks (Johnston et al., 2016). Alcohol use, binge drinking, and drunkenness among 12th graders have declined since their peak in the early 1980s.

Physical Effects of Alcohol

Alcohol depresses the central nervous system. People may think that alcohol makes one high; however, at its highest concentrations in the body it can cause death by suppressing breathing. Although this outcome is extremely rare, it may occur after chugging large quantities of alcohol, a practice that is sometimes included in certain adolescent initiation rites and drinking games. There are two other situations in which alcohol use has potentially lethal consequences. One is the use of alcohol in combination with other drugs, especially barbiturates. The other is its use in combination with driving.

The physical development accompanying puberty leads to a heightened awareness of body sensations. In small quantities, alcohol has a relaxing effect that may accentuate pleasurable bodily sensations. Adolescents may use alcohol in an attempt to increase their sense of physical arousal, reduce sexual inhibitions, and minimize the self-consciousness that is a barrier to social interactions. In larger quantities, alcohol may alter reality in such a way that adolescents are willing to take risks or ignore certain physical limitations. When adolescents are intoxicated, the barriers of physical appearance, height, weight, or sexual immaturity may be minimized. Thus, dissatisfaction with one's body image may contribute to an inclination to drink heavily in social situations.

The National Institute on Alcohol Abuse and Alcoholism provides information about the potential harm alcohol can have for health and brain functioning (NIAAA, 2016). The following information about health risks associated with underage drinking is taken from that source.

Underage drinking is associated with many deaths

Alcohol has been identified as a factor in the deaths of over 4,000 young people under age 21 each year in the U.S.

- 1,580 deaths from motor vehicle crashes
- 1,269 from homicides
- 245 from alcohol poisoning, falls, burns, and drowning
- 492 from suicides

Causes many injuries

In 2011 alone, about 188,000 people under age 21 visited an emergency room for alcohol-related injuries.

Impairs judgment

Drinking can lead to poor decisions about engaging in risky behavior, including drinking and driving, sexual activity (such as unprotected sex), and aggressive or violent behavior.

Increases the risk of physical and sexual assault

Underage drinkers are more likely to carry out or be the victim of a physical or sexual assault after drinking than others their age who do not drink.

Can lead to other problems

Drinking may cause youth to have trouble in school or with the law. Drinking alcohol also is associated with the use of other drugs.

Increases the risk of alcohol problems later in life

Research shows that people who start drinking before the age of 15 are four times more likely to meet the criteria for alcohol dependence at some point in their lives.

Interferes with brain development

Research shows that young people's brains keep developing well into their 20s. Alcohol can alter this development, potentially affecting both brain structure and function. This may cause cognitive or learning problems and/or make the brain more prone to alcohol dependence. This is especially a risk when people start drinking young and drink heavily.

Factors Associated with Alcohol Use

Consider some of the factors associated with the use of alcohol and the part it plays in the adolescent's life. We are especially concerned about understanding the relationship between alcohol use and the major themes of early adolescence—cognitive factors, motivation and emotion, parent and peer relations, and community contexts.

Cognitive Factors

Most adolescents do not view drinking alcohol as an especially risky activity. When it comes to binge drinking, however, nearly 50 percent of 12th graders consider binge drinking once or twice on weekends as very risky, and nearly 60 percent view binge drinking every day or two as very risky (Johnston et al., 2016). This perception is linked to increasing awareness of the dangers of drunk driving.

Adolescents typically see themselves as more vulnerable to negative consequences than do adults and overestimate their exposure to risks. However, with age these overestimations decline, most likely because teens have had more experiences, explored more, and may rarely encounter the negative consequences or have judged the consequences to be less serious than they expected. As a result, in the case of binge drinking, adolescents view the behavior as less risky as they get older (Reyna & Farley, 2006).

One component of the assessment of risk is concern about the anticipated future. Adolescents are increasingly able to speculate about possible futures and to consider the logical consequences of their actions. Teens are less likely to engage in binge drinking or heavy drinking if they anticipate that drinking could harm their future. This could involve physical harm, legal consequences, or harming or disappointing others (Schneider & Caffray, 2012).

Motivation and Emotion

At least four different patterns of motives and emotions have been linked to the willingness to engage in risky health behaviors, including drinking and drug use. Some adolescents can be characterized by high levels of **sensation seeking**, a tendency to pursue activities that are novel, thrilling, and exciting. Youth who have a great need for novel, complex sensory experiences may be willing to take physical risks in order to satisfy this need. Some teens are depressed; they may feel sad, lonely, worthless, or socially isolated. They engage in heavy drinking as a way to mask these feelings. Many teens experience periods of heightened tension. They are stressed as a result of school demands, parental expectations, conflicts with peers, and work. For these teens, drinking is a way to relieve stress and relax. Finally, some teens see drinking as a way to satisfy a desire for social interaction. They may be shy, they may want to impress their peers, or see drinking as part of their peer group's norms for social interaction. Social motives and a need to be part of a group can motivate drinking (Robbins & Bryan, 2004; Schneider & Caffray, 2012).

The Social Contexts of Alcohol Use

Adolescent alcohol use takes place in a complex social environment comprised of family, friends, school, and neighborhood. A study of over 6,000 adolescents ages 11 to 17 explored the importance of these four contexts in predicting alcohol misuse and how these contexts might interact to influence drinking among teens (Ennett et al., 2008). Each context made an independent contribution to the likelihood that adolescents would misuse alcohol. High levels of family conflict and alcohol use by parents were associated with a teen's drinking. Family closeness and parental supervision were associated with less drinking. In the peer context, peer modeling of drinking was associated with teens' drinking when the peer relationships were close and reciprocated. In the school and the neighborhood contexts, the most important factor was the frequency of alcohol use by students or neighbors. There was also evidence of some interaction among contexts. When family supervision was high, teens were less likely to misuse alcohol even if their friends and schoolmates were drinking. When family conflict and family alcohol use were high, teens were more likely to be influenced by their friends' and schoolmates' drinking.

Given the significance of social contexts and the socialization forces that may encourage or reward risky behavior, it is important to keep sight of the role of self-selection in alcohol and drug use as well. Some adolescents seek out friends who will support their involvement with alcohol or drugs as part of a more general pattern of deviance or thrill seeking, whereas other teens, who do not drink alcohol or use drugs, find friends who support this position. Both factors—socialization pressures toward alcohol and drug use and willingness to seek out peers who misuse drugs and alcohol—increase over the high school years, with a consequent increase in the likelihood that adolescents will become involved in the misuse of alcohol and drugs themselves (Schulenberg & Maggs, 2001). When teens are in the presence of other teens, they tend to be especially responsive to peer approval and the possible rewards of social status. If their friends are impressed by binge drinking or drunkenness, the tendency for adolescents to engage in risky alcohol use is greatly enhanced (Albert, Chein, & Steinberg, 2013).

A final aspect of the social context is the perceived availability of access to alcohol. The legal drinking age in the United States is 21. However, teens differ in their perception of how easy or difficult it is to buy alcohol in their community. Among eighth graders, about 54 percent say it is fairly easy or very easy to get alcohol. Among 12th graders, 87 percent say it is fairly easy or very easy to get alcohol in their community. Even teens who may not be willing to purchase alcohol illegally themselves are likely to know someone who will buy it for them (Johnston et al., 2016).

Although the use of many legal and illegal substances is declining, a combination of biological, psychological, and societal factors converge to make alcohol and drug use a part of the life for many adolescents during the high school years. Experimentation with alcohol is relatively easy to understand in the context of the adolescent's psychosocial needs and the modeling of alcohol use in the family, peer group, and community. Although alcohol and drug use may be considered a normative rite of passage for most adolescents, it appears that children who begin to drink or use drugs early—that is, before ninth grade—are especially vulnerable to more serious involvement with alcohol and drug use later. They experience some combination of family, peer, and psychosocial pressures that increase their willingness to engage in deviant behavior and to ignore or minimize the risks. The risk factors associated with early alcohol and drug use are linked to social class and culture. Control over the sale of alcohol to minors, its cost, and the efforts of parents and other adults—including school officials and the police—to monitor its use among adolescents are all community factors that influence the use of alcohol in early adolescence.

FURTHER REFLECTION: *A number of health-related issues have been raised in this chapter. Suppose that you were asked to provide guidance to a parents' group about how to improve health among adolescents. What ideas from this chapter might inform your recommendations?*

CHAPTER SUMMARY

Early adolescence provides vivid evidence of the interaction of the biological, psychological, and societal systems during a period of rapid growth and development.

OBJECTIVE 1 Describe the patterns of physical maturation during puberty for female and male adolescents, and analyze the impact of early and late maturing on self-concept and social relationships.

Puberty encompasses a group of interrelated neurological and endocrinological changes that influence brain development, changes in sexual maturation, cycles and levels of hormone production, and physical growth. Coming on the heels of a period of gradual but steady physical development in middle childhood, early adolescence is marked by rapid physical changes, including a height spurt, maturation of the reproductive system, appearance of secondary sex characteristics, increased muscle strength, and the redistribution of body weight. At the same time, the brain continues to develop, with changes that increase emotionality, modify memory, and gradually improve connections among areas of the brain that regulate emotion, impulse control, and judgment. Variability in the rate and sequence of development is well documented. The time from the appearance of breast buds to full maturity may range from 1 to 6 years for girls; the male genitalia may take from 2 to 5 years to reach adult size. These individual differences in maturation suggest that during early adolescence, the chronological peer group is biologically far more diverse than it was during early and middle childhood.

OBJECTIVE 2 Summarize the development of romantic and sexual relationships, and evaluate the factors that influence the transition to first intercourse, the formation of a sexual orientation, and pregnancy and parenthood in early adolescence.

Physical maturation is accompanied by new romantic feelings and sexualized experiences, some desirable and some unwanted. Most adolescents find ways to express sexual impulses in the context of socially acceptable practices. Young people are involved in a variety of romantic relationships during adolescence, including dating, feelings of tenderness and love, and deepening commitments. Adolescent dating (although not necessarily using that term) can be understood as meeting one or more central life goals, especially identity, intimacy, status, and sexuality. A majority of adolescents engage in forms of sexual behavior, including intercourse, with its accompanying risks and rewards, by the end of high school. The transition into sexual activity involves individual motivations, family and peer influences, attractiveness, and religious values and beliefs. Teens face a variety of challenges associated with their emerging sexuality. A major theme is the clarification of one's sexual orientation including awareness of sexual attractions; self-labeling as straight, lesbian, gay, bisexual, pansexual, or queer; disclosure of one's sexual orientation; and sexual experiences. Transgender youth face special challenges in connecting their gender identity with desired romantic relationships. Problems associated with sexuality include difficulty obtaining accurate and applicable sexual health information, sexual victimization, inconsistent contraception, sexually transmitted infections, and unwanted/unplanned pregnancy.

OBJECTIVE 3 Identify the basic features of formal operational thought, and explain the factors that promote the development of advanced reasoning at this period of life.

The physical changes of adolescence are taking place in a context of new and more complex cognitive capacities. Various areas of the cerebral cortex reach their peak in gray matter production during early adolescence, followed by a process of sculpting and pruning. There is a steady increase in the volume of white matter from ages 4 through the 20s. The combination of changes in gray matter and white matter in the frontal, parietal, and temporal lobes result in improvements in executive functions including working memory, planning and organizing, and impulse control. Early adolescents begin to think about themselves and their world in new ways that reflect a broadening of consciousness. This includes greater introspection or monitoring of thoughts, greater integration of information from various sources, and more focused planning and control of behaviors guided by goals and strategies. Young people are able to think about several dimensions at once rather than focusing on just one domain or issue at a time. They are able to generate hypotheses about events that they have never perceived and to use logical reasoning to evaluate evidence to support or disconfirm these hypotheses. The concept of formal operational reasoning is described, including factors that promote formal reasoning, and criticisms of this construct are reviewed. During this stage of life, the quality of experiences and the demands for higher order thinking can play a significant role in advancing a young person's cognitive abilities.

OBJECTIVE 4 Examine patterns of emotional development in early adolescence, characterize the neurological processes associated with emotional expression, and describe the nature of three problem areas: eating disorders, depression, and delinquency.

Adolescence is a time of increased emotional complexity, with new capacities to identify, understand, and express a wider range of emotions. These capacities illustrate the interdependence of cognition and emotion, including interpreting and evaluating emotional signals, and reasoning about the consequences of expressing emotions which may result in the control or management of emotional expression. The neuroscience of emotions is discussed, highlighting the emerging capacities for responding to emotionally arousing situations and new sensitivities to rewards, particularly social rewards that may motivate behavior. Emotional development is characterized by a more diverse range of emotions, greater awareness of one's emotions, and for most teens, a growing capacity to express and control the expression of emotions. After puberty, boys tend to have more externalizing problems reflecting the outward expression of anger and aggression whereas girls have more internalizing problems reflecting inward turning emotions of anxiety and depression. Three specific problem areas are described: eating disorders, depression, and delinquency.

OBJECTIVE 5 Analyze the nature of peer relations in early adolescence, especially the formation of cliques and crowds, and contrast the typical relationships with parents and peers during this stage.
